Vitamin D	A group of sterol compounds whose parent structure is cholecalciferol (vitamin D_3). Cholecalciferol is formed in the skin from 7-dehydrocholesterol (provitamin D_3) by exposure to UVB radiation. A plant sterol, ergocalciferol (provitamin D_2), can be similarly converted into vitamin D_2 and has similar vitamin D activity. The vitamin undergoes sequential hydroxylations in the liver and kidney at the 25 and 1 positions, respectively, producing the most bioactive form of the vitamin, 1,25-dihydroxy vitamin D. Vitamin D maintains intracellular and extracellular concentrations of calcium and phosphate by enhancing intestinal absorption of the two ions and, in conjunction with PTH, promoting their mobilization from bone mineral. It retards proliferation and promotes differentiation in certain epithelia. Purported actions of vitamin D as an antidiabetes, anti-inflammatory, and cancer preventive agent remain controversial and are under investigation. 1 μg = 40 IU.	Deficiency results in decreased mineralization of newly formed bone called rickets in childhood and osteomalacia in adults. Deficiency also contributes to osteoporosis and increased fracture risk in later life. Commonly appears following gastric bypass procedures. Expansion of the epiphyseal growth plates and replacement of normal bone with unmineralized bone matrix are the cardinal features of rickets; the latter feature also characterizes osteomalacia. Deformity of bone and pathologic fractures occur. Decreased serum concentrations of calcium and phosphate may occur. [15 μg, ages 19-70 yr; 20 μg, age >70 yr]	Excess amounts result in abnormally high concentrations of calcium and phosphate in the serum; metastatic calcifications, renal damage, and altered mentation may occur. [100 μg for ages ≥9 yr]	The serum concentration of the major circulating metabolite, 25-hydroxyvitamin D, is the best indicator of systemic status except in advanced kidney disease (stages 4 and 5), in which the impairment of renal 1-hydroxylation results in disassociation of the mono- and dihydroxyvitamin concentrations. Measurement of the serum concentration of 1,25-dihydroxyvitamin D is then necessary. Also, measuring free 25-hydroxyvitamin D rather than including protein-bound forms may minimize artifacts created by liver disease, sex hormones, kidney function, and genetic background.
Vitamin E	A group of at least eight naturally occurring compounds, some of which are tocopherols and some of which are tocotrienols. At present, the only dietary form that is thought to be biologically active in humans is α-tocopherol. Vitamin E acts as an antioxidant and free radical scavenger in lipophilic environments, most notably in cell membranes. It acts in conjunction with other antioxidants, such as selenium.	Deficiency due to dietary inadequacy is rare. It is usually seen in premature infants, individuals with fat malabsorption, and individuals with abetalipoproteinemia. Red blood cell fragility occurs and can produce a hemolytic anemia. Neuronal degeneration produces peripheral neuropathies, ophthalmoplegia, and destruction of posterior columns of the spinal cord. Neurologic disease is frequently irreversible if deficiency is not corrected early enough. May contribute to the hemolytic anemia and retrolental fibroplasia seen in premature infants. Reported to suppress cell-mediated immunity. [15 mg]	Depressed levels of vitamin K–dependent procoagulants and potentiation of oral anticoagulants have been reported, as has impaired WBC function. Doses of 800 mg/day have been reported to increase slightly the incidence of hemorrhagic stroke. [1000 mg]	Plasma or serum concentration of α-tocopherol is most commonly used. Additional accuracy is obtained by expressing this value per milligram of total plasma lipid. RBC peroxide hemolysis test is not entirely specific but is a useful functional measure of the antioxidant potential of cell membranes.

TABLE 199-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin K	A family of naphthoquinone compounds with similar biologic activity. Phylloquinone (vitamin K_1) is derived from plants; a variety of menaquinones (vitamin K_2) are derived from bacterial and animal sources. Vitamin K serves as an essential cofactor in the post-translational γ-carboxylation of glutamic acid residues in many proteins. These proteins include several circulating procoagulants and anticoagulants as well as proteins in a variety of tissues.	Deficiency syndrome is uncommon except in breast-fed newborns, in whom it may cause "hemorrhagic disease of the newborn," especially among newborns whose parents refuse prophylactic administration of vitamin K at birth. Also occurs in adults with fat malabsorption or who are taking drugs that interfere with vitamin K metabolism (e.g., coumarin, phenytoin, broad-spectrum antibiotics) and in individuals taking large doses of vitamin E and anticoagulant drugs. Excessive hemorrhage is the usual manifestation. [F: 90 µg; M: 120 µg]	Rapid intravenous infusion of K_1 has been rarely associated with dyspnea, flushing, and cardiovascular collapse; this is likely related to the dispersing agents in the solution. Supplementation may interfere with coumarin-based anticoagulation. Pregnant women taking large amounts of the provitamin menadione may deliver infants with hemolytic anemia, hyperbilirubinemia, and kernicterus. [No TUL established.]	Prothrombin time is typically used as a measure of functional K status; it is neither sensitive nor specific for vitamin K deficiency. Determination of fasting plasma vitamin K is an accurate indicator of status. Undercarboxylated plasma prothrombin is also an accurate metric, but only for detecting the deficient state, and is less widely available than plasma vitamin K.
WATER-SOLUBLE VITAMINS				
Thiamin (vitamin B_1)	A water-soluble compound containing substituted pyrimidine and thiazole rings and a hydroxyethyl side chain. The coenzyme form is thiamin pyrophosphate (TPP). Thiamin serves as a coenzyme in many α-ketoacid decarboxylation and transketolation reactions. Inadequate thiamin availability leads to impairments of these reactions, resulting in inadequate adenosine triphosphate synthesis and abnormal carbohydrate metabolism, respectively. It may have an additional role in neuronal conduction independent of the aforementioned actions.	Classic deficiency syndrome (beriberi) remains endemic in Asian populations consuming a polished rice diet. Globally, alcoholism, chronic renal dialysis, and persistent nausea and vomiting after bariatric surgery are also common precipitants. High carbohydrate intake increases need for B_1. Mild deficiency: irritability, fatigue, and headaches. More severe deficiency: combinations of peripheral neuropathy, cardiovascular dysfunction, and cerebral dysfunction. Cardiovascular involvement (wet beriberi): congestive heart failure and low peripheral vascular resistance. Cerebral disease: nystagmus, ophthalmoplegia, and ataxia (Wernicke encephalopathy); hallucinations, impaired short-term memory, and confabulation (Korsakoff psychosis). Deficiency syndrome responds within 24 hr to parenteral thiamin but is partially or wholly irreversible after a certain stage. [F: 1.1 mg; M: 1.2 mg]	Excess intake is largely excreted in the urine, although parenteral doses of >400 mg/day are reported to cause lethargy, ataxia, and reduced tone of the gastrointestinal tract. [TUL not established.]	The most effective measure of B_1 status is the erythrocyte transketolase activity coefficient, which measures enzyme activity before and after addition of exogenous TPP; RBCs from a deficient individual express a substantial increase in enzyme activity with addition of TPP. Thiamin concentrations in blood or urine are also used.
Riboflavin (vitamin B_2)	Consists of a substituted isoalloxazine ring with a ribitol side chain. Riboflavin serves as a coenzyme for a diverse array of biochemical reactions. The primary coenzymatic forms are flavin mononucleotide and flavin adenine dinucleotide. Riboflavin holoenzymes participate in oxidation-reduction reactions in myriad metabolic pathways.	Deficiency is usually seen in conjunction with deficiencies of other B vitamins. Isolated deficiency of riboflavin produces hyperemia and edema of nasopharyngeal mucosa, cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, and a normochromic, normocytic anemia. [F: 1.1; M: 1.3]	Toxicity is not reported in humans. [TUL not established.]	The most common method of assessment is to determine the activity coefficient of glutathione reductase in RBCs (the test is invalid for individuals with glucose-6-phosphate dehydrogenase deficiency). Measurements of blood and urine concentrations are less desirable methods.

TABLE 199-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Niacin (vitamin B_3)	Refers to nicotinic acid and the corresponding amide, nicotinamide. The active coenzymatic forms are composed of nicotinamide affixed to adenine dinucleotide, forming NAD or NADP. More than 200 apoenzymes use these compounds as electron acceptors or hydrogen donors, either as a coenzyme or as a co-substrate. The essential amino acid tryptophan is a precursor of niacin; 60 mg of dietary tryptophan yields approximately 1 mg of niacin. Dietary requirements thus depend partly on tryptophan intake. Requirement is often determined on basis of calorie intake (i.e., niacin equivalents/1000 kcal). Large doses of nicotinic acid (1.5-3 g/day) effectively lower low-density lipoprotein cholesterol and elevate high-density lipoprotein cholesterol.	*Pellagra* is the classic deficiency syndrome and is often seen in populations in which corn is the major source of energy; it is still endemic in parts of China, Africa, and India. Diarrhea, dementia (or associated symptoms of anxiety or insomnia), and a pigmented dermatitis that develops in sun-exposed areas are typical features. Glossitis, stomatitis, vaginitis, vertigo, and burning dysesthesias are early signs. It is reported occasionally to occur in carcinoid syndrome because tryptophan is diverted to other synthetic pathways. [F: 14 mg; M: 16 mg]	Human toxicity is known largely through studies examining hypolipidemic effects. Includes vasomotor phenomenon (flushing), hyperglycemia, parenchymal liver damage, and hyperuricemia. [35 mg]	Assessment of status is problematic; blood levels of the vitamin are not reliable. Measurement of urinary excretion of the niacin metabolites *N*-methylnicotinamide and 2-pyridone is thought to be the most effective means of assessment at present.
Vitamin B_6	Refers to several derivatives of pyridine, including pyridoxine, pyridoxal, and pyridoxamine, which are interconvertible in the body. The coenzymatic forms are pyridoxal-5-phosphate (PLP) and pyridoxamine-5-phosphate. As a coenzyme, B_6 is involved in many transamination reactions (and thereby in gluconeogenesis), in the synthesis of niacin from tryptophan, in the synthesis of several neurotransmitters, and in the synthesis of δ-aminolevulinic acid (and therefore in heme synthesis). It also has functions unrelated to coenzymatic activity: pyridoxal and PLP bind to hemoglobin and alter oxygen affinity; PLP also binds to steroid receptors, inhibiting receptor affinity to DNA and thereby modulating steroid activity.	Deficiency is usually seen in conjunction with other water-soluble vitamin deficiencies. Stomatitis, angular cheilosis, glossitis, irritability, depression, and confusion occur in moderate to severe depletion; normochromic, normocytic anemia has been reported in severe deficiency. Abnormalities on electroencephalography and, in infants, convulsions have also been observed. Some sideroblastic anemias respond to B_6 administration. Isoniazid, cycloserine, penicillamine, ethanol, and theophylline can inhibit B_6 metabolism. [Ages 19-50 yr: 1.3 mg; >50 yr: 1.5 mg for women, 1.7 mg for men]	Long-term use with doses exceeding 200 mg/day (in adults) may cause peripheral neuropathies and photosensitivity. [100 mg]	Many useful laboratory methods of assessment exist. The plasma or erythrocyte PLP levels are most common. Urinary excretion of xanthurenic acid after an oral tryptophan load and activity indices of RBC alanine or aspartate transaminase are functional measures of B_6-dependent enzyme activity.
Folate	A group of related pterin compounds. More than 35 forms of the vitamin are found naturally. The fully oxidized form, folic acid, is not found in nature but is the pharmacologic form of the vitamin used in supplements and fortification programs. All folate functions relate to its ability to transfer one-carbon groups. It is essential in the de novo synthesis of nucleotides and in the metabolism of several amino acids; it is an integral component for the regeneration of the "universal" methyl donor, *S*-adenosylmethionine. Inhibition of bacterial and cancer cell folate metabolism is the basis for the sulfonamide antibiotics and chemotherapeutic agents, such as methotrexate and 5-fluorouracil, respectively.	Women of childbearing age are most likely to be deficient. Classic deficiency syndrome: megaloblastic anemia, diarrhea. The hematopoietic cells in bone marrow become enlarged and have immature nuclei, reflecting ineffective DNA synthesis. The peripheral blood smear demonstrates macro-ovalocytes and polymorphonuclear leukocytes with an average of more than 3.5 nuclear lobes. Megaloblastic changes also occur in other epithelia that proliferate rapidly (e.g., oral mucosa and gastrointestinal tract, producing glossitis and diarrhea, respectively). Sulfasalazine and diphenytoin inhibit absorption and predispose to deficiency. [400 μg of dietary folate equivalents (DFE); 1 DFE = 1 μg food folate = 0.6 μg folic acid]	Doses >1000 μg/day may partially correct the anemia of B_{12} deficiency and may therefore mask (and perhaps exacerbate) the associated neuropathy. Large doses are also reported to lower seizure threshold in individuals prone to seizures. Parenteral administration is rarely reported to cause allergic phenomena, which is probably due to dispersion agents. [1000 μg]	Serum folate measures short-term folate balance, whereas RBC folate is a better reflection of tissue status. Serum homocysteine rises early in deficiency but is nonspecific because B_{12} or B_6 deficiency, renal insufficiency, and older age may also cause elevations.

TABLE 199-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin C (ascorbic and dehydroascorbic acid)	Ascorbic acid readily oxidizes to dehydroascorbic acid in aqueous solution. Dehydroascorbic acid can be reduced in vivo, so it possesses vitamin C activity. Total vitamin C is therefore the sum of ascorbic and dehydroascorbic acid content. Vitamin C serves primarily as a biologic antioxidant in aqueous environments. Biosyntheses of collagen, carnitine, bile acids, and norepinephrine, as well as proper functioning of the hepatic mixed-function oxygenase system, depend on this property. Vitamin C in foodstuffs increases the intestinal absorption of nonheme iron.	Overt deficiency is uncommon in developed countries. The classic deficiency syndrome is *scurvy:* fatigue, depression, and widespread abnormalities in connective tissues, such as inflamed gingivae, petechiae, perifollicular hemorrhages, impaired wound healing, coiled hairs, hyperkeratosis, and bleeding into body cavities. In infants, defects in ossification and bone growth may occur. Tobacco smoking lowers plasma and leukocyte vitamin C levels. [F: 75 mg; M: 90 mg; increase requirement for cigarette smokers by 35 mg/day]	≥500 mg/day (in adults) may cause nausea and diarrhea. >1 g/day modestly increases risk for oxalate kidney stones. Supplementation may interfere with laboratory tests based on redox potential (e.g., fecal occult blood testing, serum cholesterol, and glucose). Withdrawal from chronic ingestion of high doses of vitamin C supplements should be done gradually because accommodation appears to occur, raising a concern of "rebound scurvy." [2 g]	Plasma ascorbic acid concentration reflects recent dietary intake, whereas WBC levels more closely reflect tissue stores. Women's plasma levels are approximately 20% higher than men's for any given dietary intake.
Vitamin B_{12}	A group of closely related cobalamin compounds composed of a corrin ring (with a cobalt atom in its center) connected to a ribonucleotide through an aminopropanol bridge. Microorganisms are the ultimate source of all naturally occurring B_{12}. The two active coenzyme forms are deoxyadenosylcobalamin and methylcobalamin. These coenzymes are needed for the synthesis of succinyl CoA, which is essential in lipid and carbohydrate metabolism, and for the synthesis of methionine. The synthesis of methionine is essential for amino acid metabolism, for purine and pyrimidine synthesis, for many methylation reactions, and for the intracellular retention of folates.	Dietary inadequacy is a rare cause of deficiency except in strict vegetarians. Most deficiencies arise from loss of intestinal absorption, which may occur with pernicious anemia, pancreatic insufficiency, atrophic gastritis, small bowel bacterial overgrowth, or ileal disease. Megaloblastic anemia and megaloblastic changes in epithelia (see Folate) are the result of sustained depletion. Demyelination of peripheral nerves, posterior and lateral columns of the spinal cord, and nerves within the brain may occur. Altered mentation, depression, and psychoses occur. Hematologic and neurologic complications may occur independently. Folate supplementation, in doses of 1000 µg/day, may partly correct the anemia, thereby masking (or perhaps exacerbating) the neuropathic complication. [2.4 µg]	A few allergic reactions have been reported to crystalline B_{12} preparations and are probably due to impurities, not the vitamin. [TUL not established.]	Serum or plasma B_{12} concentrations are generally accurate, although subtle deficiency with neurologic and/or hematologic complications can occur with levels in the low-normal range (148-258 pmol/L or 200–350 pg/mL). In this setting deficiency can be established by concurrently measuring the concentration of plasma B_{12} and serum methylmalonic acid, which is a sensitive indicator of cellular deficiency. This subtle deficiency state has been increasingly recognized among older populations. Serum holotranscobalamin is another metric, although it is not clearly superior to plasma B_{12}.
Biotin	A bi-cyclic compound consisting of a ureido ring fused to a substituted tetrahydrothiophene ring. Endogenous synthesis by intestinal flora may contribute significantly to biotin nutriture. Most dietary biotin is linked to lysine, a compound called biotinyl lysine, or biocytin. The lysine must be hydrolyzed by an intestinal enzyme called biotinidase before intestinal absorption occurs. Biotin acts primarily as a coenzyme for several carboxylases; each holoenzyme catalyzes an adenosine triphosphate–dependent carbon dioxide transfer. The carboxylases are critical enzymes in carbohydrate and lipid metabolism.	Isolated deficiency is rare. Deficiency in humans has been produced by prolonged total parenteral nutrition lacking the vitamin and by ingestion of large quantities of raw egg white, which contains avidin, a protein that binds biotin with such high affinity that it renders it biounavailable. Alterations in mental status, myalgias, hyperesthesias, and anorexia occur. Later, a seborrheic dermatitis and alopecia develop. Deficiency is usually accompanied by lactic acidosis and organic aciduria. [30 µg]	Toxicity has not been reported in humans with doses as high as 60 mg/day in children. [TUL not established.]	Plasma and urine concentrations of biotin are diminished in the deficient state. Elevated urine concentrations of methyl citrate, 3-methylcrotonylglycine, and 3-hydroxyisovalerate are also observed in deficiency.

TABLE 199-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Pantothenic acid	Consists of pantoic acid linked to β-alanine through an amide bond. Pantothenic acid is an essential component of CoA and phosphopantetheine, which are essential for synthesis and β-oxidation of fatty acids as well as for synthesis of cholesterol, steroid hormones, vitamins A and D, and other isoprenoid derivatives. CoA is also involved in the synthesis of several amino acids and δ-aminolevulinic acid, a precursor for the corrin ring of vitamin B_{12}, the porphyrin ring of heme, and of cytochromes. CoA is also necessary for the acetylation and fatty acid acylation of a variety of proteins.	Deficiency is rare; it has been reported only as a result of feeding of semisynthetic diets or consumption of an antagonist such as calcium homopantothenate (which has been used to treat Alzheimer disease). Experimental, isolated deficiency in humans produces fatigue, abdominal pain, vomiting, insomnia, and paresthesias of the extremities. [5 mg]	In doses of 10 g/day, diarrhea is reported to occur. [TUL not established.]	Whole blood and urine concentrations of pantothenate are indicators of status; serum levels are not thought to be accurate.

*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001 (updated in 2010 for vitamin D and calcium). In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.

†Tolerable upper limit (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.

CoA = coenzyme A; F = female; M = male; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; PLP = pyridoxal phosphate; PTH = parathyroid hormone; RBC = red blood cell; TUL = tolerable upper limit; UVB = ultraviolet B; WBC = white blood cell.

TABLE 199-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Chromium	Dietary chromium consists of both inorganic and organic forms. Its primary function in humans is to potentiate insulin action. It accomplishes this function as a circulating complex called *glucose tolerance factor*, thereby affecting carbohydrate, fat, and protein metabolism.	Deficiency in humans has been described only in long-term total parenteral nutrition (TPN) patients receiving insufficient chromium. Hyperglycemia or impaired glucose tolerance occurs. Elevated plasma free fatty acid concentrations, neuropathy, encephalopathy, and abnormalities in nitrogen metabolism are also reported. Whether supplemental chromium may improve glucose tolerance in glucose-intolerant individuals remains controversial. [F: 25 μg; M: 35 μg]	Toxicity after oral ingestion is uncommon and seems confined to gastric irritation. Airborne exposure may cause contact dermatitis, eczema, skin ulcers, and bronchogenic carcinoma. [No TUL established.]	Plasma or serum concentration of chromium is a crude indicator of chromium status; it appears to be meaningful when the value is markedly above or below the normal range.
Copper	Copper is absorbed by a specific intestinal transport mechanism. It is carried to the liver, where it is bound to ceruloplasmin, which circulates systemically and delivers copper to target tissues in the body. Excretion of copper is largely through bile and then into the feces. Absorptive and excretory processes vary with the levels of dietary copper, providing a means of copper homeostasis. Copper serves as a component of many enzymes, including amine oxidases, ferroxidases, cytochrome *c* oxidase, dopamine β-hydroxylase, superoxide dismutase, and tyrosinase.	Dietary deficiency is rare; it has been observed in premature and low-birthweight infants fed exclusively a cow's milk diet and in individuals on long-term TPN lacking copper. It has also been described after gastric bypass surgery and with chronic zinc supplementation. Clinical manifestations include depigmentation of skin and hair, myelopathy and other neurologic lesions, leukopenia, anemia, and skeletal abnormalities. Anemia arises from impaired utilization of iron and therefore often is manifested as a sideroblastic anemia. The peripheral smear and bone marrow may mimic myelodysplasia. A deficiency syndrome is also observed in Menkes disease, a rare inherited condition associated with impaired copper utilization. [900 μg]	Acute copper toxicity has been described after excessive oral intake and with absorption of copper salts applied to burned skin. Milder manifestations include nausea, vomiting, epigastric pain, and diarrhea; coma and hepatic necrosis may ensue in severe cases. Toxicity may be seen with doses as low as 70 μg/kg/day. Chronic toxicity is also described. Wilson disease is a rare, inherited disease associated with abnormally low ceruloplasmin levels and accumulation of copper in the liver and brain, eventually leading to damage to these two organs. [10 mg]	Practical methods to detect marginal deficiency are not available. Marked deficiency is reliably detected by diminished serum copper and ceruloplasmin concentrations as well as by low red blood cell superoxide dismutase activity.

TABLE 199-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Fluorine	Known more commonly by its ionic form, fluoride. Fluorine is incorporated into the crystalline structure of bone, thereby altering its physical characteristics. Fluoridation of water has reduced incidence of caries in communities with fluoridation programs.	Intake of <0.1 mg/day in infants and <0.5 mg/day in children is associated with an increased incidence of dental caries. Optimal intake in adults is between 1.5 and 4 mg/day. [F: 3 mg; M: 4 mg]	Acute ingestion of >30 mg/kg body weight is likely to cause death. Excessive chronic intake (0.1 mg/kg/day) leads to mottling of teeth (dental fluorosis), calcification of tendons and ligaments, and exostoses and may increase the brittleness of bones. [10 mg]	Estimates of intake and clinical assessment are used because no good laboratory test exists.
Iodine	Iodine is readily absorbed from the diet, concentrated in the thyroid, and integrated into the thyroid hormones thyroxine and triiodothyronine. These hormones circulate largely bound to thyroxine-binding globulin. They modulate resting energy expenditure and, in the developing human, growth and development.	In the absence of supplementation, populations relying primarily on food from soils with low iodine content have endemic iodine deficiency. Maternal iodine deficiency leads to fetal deficiency, which produces spontaneous abortions, stillbirths, hypothyroidism, cretinism, and dwarfism. Permanent cognitive deficits may result from iodine deficiency during the first 2 years of life. In the adult, compensatory hypertrophy of the thyroid (goiter) occurs along with varying degrees of hypothyroidism. [150 µg]	Large doses (>2 mg/day in adults) may induce hypothyroidism by blocking thyroid hormone synthesis. Supplementation with >100 mg/day to an individual who was formerly deficient occasionally induces hyperthyroidism. [1.1 mg]	Iodine status of a population can be estimated by the prevalence of goiter. Urinary excretion of iodine is an effective laboratory means of assessment. Thyroid-stimulating hormone blood level is an indirect and therefore not entirely specific means of assessment.
Iron	Conveys the capacity to participate in redox reactions to a number of metalloproteins, such as hemoglobin, myoglobin, cytochrome enzymes, and many oxidases and oxygenases. The primary storage form of iron is ferritin and, to a lesser degree, hemosiderin. Intestinal absorption is 15-20% for "heme" iron and 1-8% for iron contained in vegetables. Absorption of the latter form is enhanced by the ascorbic acid in foodstuffs; by poultry, fish, or beef; and by an iron-deficient state. It is decreased by phytate and tannins.	Iron deficiency is the most common micronutrient deficiency in the world. Women of childbearing age are the group at highest risk because of menstrual blood losses, pregnancy, and lactation. The classic deficiency syndrome is hypochromic, microcytic anemia. Glossitis and koilonychia ("spoon" nails) are also observed. Easy fatigability often is an early symptom, before anemia appears. In children, mild deficiency of insufficient severity to cause anemia is associated with behavioral disturbances and poor school performance. [postmenopausal F and M: 8 mg; premenopausal F: 18 mg]	Iron overload typically occurs when habitual dietary intake is extremely high, intestinal absorption is excessive, repeated parenteral administration occurs, or a combination of these factors exists. Excessive iron stores usually accumulate in the reticuloendothelial tissues and cause little damage (hemosiderosis). If overload continues, iron eventually begins to accumulate in tissues such as the hepatic parenchyma, pancreas, heart, and synovium, causing hemochromatosis (Chapter 196). Hereditary hemochromatosis results from homozygosity of a common recessive trait. Excessive intestinal absorption of iron is seen in homozygotes. [45 mg]	Negative iron balance initially leads to depletion of iron stores in the bone marrow; a bone marrow biopsy and the concentration of serum ferritin are accurate indicators of early depletion. As the severity of deficiency proceeds, serum iron (SI) decreases and total iron-binding capacity (TIBC) increases; an iron saturation (SI/TIBC) of <16% suggests iron deficiency. Microcytosis, hypochromia, and anemia ensue. Elevated levels of serum ferritin or an iron saturation of >60% suggests iron overload, although systemic inflammation elevates serum ferritin regardless of iron status.
Manganese	A component of several metalloenzymes. Most manganese is in mitochondria, where it is a component of manganese superoxide dismutase.	Manganese deficiency in the human has not been conclusively demonstrated. It is said to cause hypocholesterolemia, weight loss, hair and nail changes, dermatitis, and impaired synthesis of vitamin K–dependent proteins. [F: 1.8 mg; M: 2.3 mg]	Toxicity by oral ingestion is unknown in humans. Toxic inhalation causes hallucinations, other alterations in mentation, and extrapyramidal movement disorders. [11 mg]	Until the deficiency syndrome is better defined, an appropriate measure of status will be difficult to develop.
Molybdenum	A cofactor in several enzymes, most prominently xanthine oxidase and sulfite oxidase.	A probable case of human deficiency is described as being secondary to parenteral administration of sulfite and resulted in hyperoxypurinemia, hypouricemia, and low sulfate excretion. [45 µg]	Toxicity not well described in humans, although it may interfere with copper metabolism at high doses. [2 mg]	Laboratory means of assessment are not meaningful until the deficiency syndrome is better described.

TABLE 199-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Selenium	Most dietary selenium is in the form of an amino acid complex. Nearly complete absorption of such forms occurs. Homeostasis is largely performed by the kidney, which regulates urinary excretion as a function of selenium status. Selenium is a component of several enzymes, most notably glutathione peroxidase and superoxide dismutase. These enzymes protect against oxidative and free radical damage of various cell structures. The antioxidant protection conveyed by selenium apparently operates in conjunction with vitamin E because deficiency of one seems to potentiate damage induced by a deficiency of the other. Selenium also participates in the enzymatic conversion of thyroxine to its more active metabolite, triiodothyronine.	Deficiency is rare in North America but has been observed in individuals on long-term TPN lacking selenium. Such individuals have myalgias or cardiomyopathies. Populations in some regions of the world, most notably some parts of China, have marginal intake of selenium. In these regions *Keshan disease*, a condition characterized by cardiomyopathy, is endemic; it can be prevented (but not treated) by selenium supplementation. [55 µg]	Toxicity is associated with nausea, diarrhea, alterations in mental status, peripheral neuropathy, and loss of hair and nails; such symptoms were observed in adults who inadvertently consumed 27-2400 mg. [400 µg]	Erythrocyte glutathione peroxidase activity and plasma or whole blood selenium concentrations are the most commonly used methods of assessment. They are moderately accurate indicators of status.
Zinc	Intestinal absorption occurs by a specific process that is enhanced by pregnancy and corticosteroids and diminished by coingestion of phytates, phosphates, iron, copper, lead, or calcium. Diminished intake of zinc leads to an increased efficiency of absorption and decreased fecal excretion, providing a means of zinc homeostasis. Zinc is a component of more than 100 enzymes, among which are DNA polymerase, RNA polymerase, and transfer RNA synthetase.	Zinc deficiency has its most profound effect on rapidly proliferating tissues. Mild deficiency: growth retardation in children. More severe deficiency: growth arrest, teratogenicity, hypogonadism and infertility, dysgeusia, poor wound healing, diarrhea, dermatitis on the extremities and around orifices, glossitis, alopecia, corneal clouding, loss of dark adaptation, and behavioral changes. Impaired cellular immunity is observed. Excessive loss of gastrointestinal secretions through chronic diarrhea and fistulas may precipitate deficiency. *Acrodermatitis enteropathica* is a rare, recessively inherited disease in which intestinal absorption of zinc is impaired. [F: 8 mg; M: 11 mg]	Acute zinc toxicity can usually be induced by ingestion of >200 mg of zinc in a single day (in adults). It is manifested by epigastric pain, nausea, vomiting, and diarrhea. Hyperpnea, diaphoresis, and weakness may follow inhalation of zinc fumes. Copper and zinc compete for intestinal absorption: long-term ingestion of >25 mg/day of zinc may lead to copper deficiency. Long-term ingestion of >150 mg/day has been reported to cause gastric erosions, low high-density lipoprotein cholesterol levels, and impaired cellular immunity. [40 mg]	No accurate indicators of zinc status exist for routine clinical use. Plasma, red blood cell, and hair zinc concentrations are often misleading. Acute illness, in particular, is known to diminish plasma zinc levels, in part by inducing a shift of zinc out of the plasma compartment and into the liver. Functional tests that determine dark adaptation, taste acuity, and rate of wound healing lack specificity.

*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001. In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.
†Tolerable upper limit (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.

TOXINS

Tobacco smoking (Chapter 363) alters the metabolism of several vitamins, including folate and vitamins C and E. Diminished plasma levels of folate and ascorbic acid also have been observed in chronic smokers. Smoking is also associated with diminished levels of folate in cells of the oral mucosa, diminished ascorbic acid levels in leukocytes, and decreased concentrations of vitamin E in the alveolar fluid, thereby indicating that its effects do not simply represent a shift of these micronutrients out of the plasma compartment.

CONTROVERSIES REGARDING MARGINAL MICRONUTRIENT DEFICIENCIES

In a number of circumstances, micronutrient supplementation can improve a physiologic measurement but not to provide overall clinical benefit, especially when used in supraphysiologic doses. For example, gram quantities of niacin can reduce low-density lipoprotein (LDL) cholesterol levels but may marginally increase all-cause mortality.[A3,4]

Examples of the complexities in redefining the criteria for vitamin deficiencies and vitamin requirements are two water-soluble vitamins, folate and B_{12}. Degrees of deficiency that are not sufficiently severe to cause anemia (Chapter 150) may still disturb normal biochemical and physiologic homeostasis and, in some instances, cause clinical disease.

For example, women who take folic acid supplements at the time of conception have a markedly lower chance of delivering a baby with a neural tube defect compared with women who are not taking folate supplements, even if they have a folate level within the conventionally accepted normal range. Less-than-optimal intake of folate is also evidenced by an increase in the serum level of homocysteine, which is an amino acid that is normally metabolized by a folate-dependent pathway (Chapter 193). Before the federally mandated fortification of flour, the median intake of folate among adults was half of the present RDA, and a substantial minority of Americans had significantly elevated serum homocysteine levels. An elevated homocysteine level (Chapter 193), which is associated with the development of occlusive vascular disease and accelerated cognitive decline, can be reduced with supplemental folate, vitamin B_{12}, and vitamin B_6. A moderate level of evidence indicates supplemental folate may decrease the risk of stroke, but the risks of coronary artery and peripheral vascular disease are not diminished.

A compelling body of rigorously performed epidemiologic studies has demonstrated that habitually low consumption of folate is associated with a substantially increased risk of colorectal cancer, and mechanistic animal studies support true causality. The optimal folate intake in regard to cancer prevention is unclear, but epidemiologic studies suggest the value is about 500 µg per day. The question of optimal intake is further confounded by

TABLE 199-4 DRUG-MEDIATED EFFECTS ON MICRONUTRIENT STATUS: EXAMPLES

DRUG	NUTRIENT	MECHANISM OF INTERACTION
Dextroamphetamine, levodopa	Potentially all micronutrients	Induces anorexia
Proton pump inhibitors, H2-histamine antagonists	Vitamin B_{12}	Modest bacterial overgrowth, decreases gastric acid, impairs absorption
Metformin	Vitamin B_{12}	Impairs absorption
Isoniazid	Vitamin B_6	Impairs utilization of B_6
Nonsteroidal anti-inflammatory drugs	Iron	Gastrointestinal blood loss
Penicillamine	Zinc	Increases renal excretion
Cholestyramine and related drugs	Vitamin D, folate	Adsorbs nutrient, decreases absorption

observations that doses of supplemental folic acid exceeding 1000 µg/day may mask B_{12} deficiency and may paradoxically enhance the risk of colorectal cancer, thereby underscoring the potential for harm produced by taking a nutrient outside of its physiologic window.[5] Presently, the recommended daily intake of folate is 400 µg/day, and women capable of becoming pregnant should consume an additional 400 µg/day in the form of supplements or fortified food. The tolerable upper limit is 1000 µg/day, and continuing research efforts will hopefully clarify any potential role for what constitutes ideal folic acid consumption and levels

For vitamin B_{12} (see Chapter 150), a plasma level between 200 and 350 pg/mL, which is at the lower end of the normal range in most laboratories, may not exclude neuropsychiatric complications, even in the absence of any indications of megaloblastic anemia, especially in older adults who have a higher prevalence of atrophic gastritis and use of medications (gastric acid suppressants and metformin) that reduce B_{12} absorption.[6] In such individuals, an elevated serum level of methylmalonic acid is both a sensitive and a specific indicator of cellular vitamin B_{12} deficiency, and vitamin B_{12} repletion (see Chapter 150) should be prescribed to lower the methylmalonic acid level to normal. However, routine vitamin B_{12} supplementation in individuals with an adequate B_{12} status has no effect on cognitive function, depressive symptoms, or fatigue.[A4]

IS ROUTINE MULTIVITAMIN AND MULTIMINERAL SUPPLEMENTATION BENEFICIAL?

In recent surveys of U.S. adults, use of supplements, including vitamins and minerals, remains high: about 60% of adults ages 20 years and older report use of a supplement in the past month, and the percentage is about 75% among adults ages 60 years and over. Among this older cohort, 25% of individuals report the use of four or more supplements. Despite the absence of unanimous consensus about whether regular use of a multivitamin or multimineral supplement assists in the maintenance of health, the weight of current evidence indicates little or no benefit from micronutrient supplementation in the general adult North American population in terms of preventing common chronic degenerative diseases such as vascular disease, cancer, and dementia.

Poor dietary patterns are often observed among individuals of lower socioeconomic status. Moreover, in many regions of the world, there continues to be a high prevalence of marginal micronutrient status among the general adult population, and in such areas widespread supplementation may be indicated.

The elderly frequently cannot achieve recommended intakes of vitamin D and calcium to optimize bone health with diet alone, and a plasma 25-hydroxy vitamin D level below 20 ng/L has been associated with increased mortality.[7] Targeted supplementation with vitamin D (400 to 800 IU daily) plus calcium (1000 mg) can reduce the risk of fractures[A5] and is often indicated for this purpose (see Chapter 225).[8] However, meta-analyses of randomized trials of vitamin D supplementation have shown no benefit for preventing cancer or cardiovascular events,[A6] depression,[A7] tuberculosis infection,[A8] or the outcomes of critically ill patients who are vitamin D deficient.[A9] Whether vitamin supplementation retards the progression from pre-diabetes to diabetes remains a matter of controversy.[9,A10] Routine screening for vitamin deficiency is not recommended by the U.S. Preventive Services Task Force,[10] but a vitamin D level should be obtained in high-risk individuals, including whenever a pathologic fracture has occurred.

Although daily supplementation at the levels found in most multivitamin preparations probably presents no risk of harm, vitamin and mineral supplements are of no proven benefit for preventing cardiovascular disease or cancer.[A11,11] Vitamin C supplementation is of no benefit for adults with sepsis[A12] or severe infection.[A13]

Furthermore, adverse health effects have been observed in several rigorously performed clinical trials of long-term supplementation with micronutrients at levels that exceed the RDA (or conventional levels of dietary intake) by several-fold. For example, an increased incidence of prostate cancer was observed when vitamin E was administered at a dose of 400 IU/day, and β-carotene supplementation resulted in an increased incidence of lung cancer among heavy smokers in doses of 20 to 30 mg/day.

Nevertheless, health benefits are likely in individuals whose dietary intake is chronically inadequate or in patients whose medical conditions are predictably complicated by micronutrient deficiencies, such as patients on chronic renal dialysis (Chapter 116), individuals with marginally controlled intestinal malabsorption (Chapter 126), and pregnant women.

New biochemical functions of vitamins are increasingly being recognized, and the quantities of each micronutrient that are required to optimize such functions may need to be considered. Also, future efforts to refine appropriate dietary goals for each micronutrient will have to consider whether the level of consumption that conveys health benefits to one segment of the population is beneficial, or even appropriate, for all segments of society, thereby underscoring the importance of personalized medicine.

200 EATING DISORDERS

EVELYN ATTIA, MARIAN TANOFSKY-KRAFF, AND B. TIMOTHY WALSH

DEFINITION

Feeding and eating disorders are characterized by a persistent disturbance of eating or eating-related behavior that results in the altered consumption or absorption of food and that significantly impairs physical health or psychosocial functioning.[1] The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5)[2] provides formal criteria defining anorexia nervosa, bulimia nervosa, binge-eating disorder, and avoidant/restrictive food intake disorder. Presentations that do not meet criteria for any of these specific diagnoses but that cause significant distress or impairment can be described as other feeding or eating disorders.

Anorexia Nervosa

The salient feature of anorexia nervosa is the restriction of caloric intake, thereby resulting in a significantly low body weight. Individuals with anorexia nervosa experience an intense fear of gaining weight or becoming fat, are overly concerned with weight or shape, and often do not recognize the seriousness of their low body weight. Anorexia nervosa has two subtypes, restricting and binge-eating/purging.

Bulimia Nervosa

Bulimia nervosa is characterized by recurrent episodes of binge eating (i.e., the consumption of an unambiguously large amount of food given the context), accompanied by a sense of loss of control over eating. Episodes of binge eating are followed by behaviors intended to compensate for energy consumed and to prevent weight gain, such as self-induced vomiting and laxative abuse. Binge-eating and compensatory behaviors must occur, on average, at least once a week for 3 months. The self-esteem of individuals with bulimia nervosa is excessively influenced by their body weight and shape.

Binge-Eating Disorder

Individuals with binge-eating disorder engage in recurrent episodes of binge eating but in the absence of the inappropriate compensatory behaviors that characterize bulimia nervosa. The binge episodes are accompanied by at least three associated indicators of loss of control, such as eating very rapidly and eating until feeling uncomfortably full. Individuals experience marked distress surrounding the binge episodes, and the binge-eating episodes occur, on average, at least once a week for 3 months.

Avoidant/Restrictive Food Intake Disorder

Individuals with avoidant/restrictive food intake disorder significantly restrict their food intake but do not have the major concerns about body shape and weight that are seen in individuals with anorexia nervosa. Individuals may avoid food generally or may avoid foods with specific characteristics, such as color or texture.

Pica

Pica refers to the persistent and age-inappropriate consumption of nonfood substances, such as dirt, paper, or soap.

Rumination Disorder

Rumination disorder is characterized by the repeated regurgitation of food after eating. The food may then be re-chewed, re-swallowed, or spit out.

EPIDEMIOLOGY

The lifetime prevalence of anorexia nervosa is approximately 0.8%, with higher rates among women (1.4%) compared with men (0.12%). The lifetime prevalence of bulimia nervosa appears to be about 0.3%, with higher rates among women (5%) than men (0.1%). The lifetime prevalence of binge-eating disorder is estimated at 1.3% for women and 0.4% for men. Contrary to the view that eating disorders afflict only non-Hispanic White, affluent females, individuals of all races, ethnicities, and cultures are impacted by these diagnoses. Female sex, age, presence of eating disorders in siblings and comorbid disorders in family members, pediatric overweight, inappropriate concerns about body shape and weight, sexual abuse, trauma, and mood disorders are risk factors for eating disorders.

Personality-related variables, such as impulsivity and perfectionism, also appear to be linked to eating disorders. Internalization of the "thin ideal" (a sociocultural emphasis on shape and weight and a marked preference for a thin body type) and resulting weight and shape concerns have been proposed to contribute to eating disorder development, particularly among adolescents who are under strong influence from their peer and family environments. For example, parental over-concern about eating, shape, and weight, as well as weight-related teasing by family members, confers risk for eating disorders. Teasing and bullying are specific risk factors for bulimia nervosa and binge-eating disorder

PATHOBIOLOGY

A detailed understanding of the relationship between brain structural and functional abnormalities and the development, severity, and course of eating disorders is lacking.[3] Most research on the neurobiology of eating disorders has focused on anorexia nervosa and bulimia nervosa. Structural brain imaging has found that patients with anorexia nervosa have reduced volumes of gray and white matter, which generally normalize with restoration of weight. Several studies have described decreased cortical thickness in frontal and parietal regions, with suggestions that decreased cortical thickness is associated with greater disturbances in eating behavior.

Individuals with anorexia nervosa tend to show decreased brain responses to images of food and to sweet tastes compared with healthy controls, but precisely how such differences are related to the core disturbance in eating behavior is less clear. When making decisions about what to eat, individuals with anorexia nervosa engage the dorsal striatum, an area associated with habitual behavior, more than healthy controls. Neurocognitive tasks indicate deficiencies in inhibitory control mechanisms, particularly to food cues.

Anorexia nervosa, bulimia nervosa, and binge-eating disorder aggregate in families,[4] with estimates from twin studies suggesting that 40 to 60% of vulnerability for eating disorders is genetic. The most extensive genetic studies have focused on anorexia nervosa, for which eight loci have been identified, but the number of loci is expected to increase as more studies are performed.

CLINICAL MANIFESTATIONS

Anorexia Nervosa

Anorexia nervosa typically manifests during adolescence, although the disorder can develop prior to puberty. Individuals with anorexia nervosa may develop a wide range of physical symptoms and signs largely related to starvation.[5] Individuals with anorexia nervosa frequently present with symptoms of other psychiatric disorders (Chapter 362), including obsessionality, anxiety, and depression, as well as with high rates of suicidal ideation and behavior. Symptoms include fatigue, constipation, and intolerance to cold. Hypogonadism with amenorrhea (Chapter 218) is nearly universal in females. In addition to wasting, the physical examination may reveal lanugo hair and hypercarotenemia.

Health problems associated with malnutrition impact the cardiovascular, gastrointestinal, reproductive, hematologic, and endocrine systems.[6] Hypotension and sinus bradycardia are characteristic findings. However, patients with anorexia nervosa can also develop arrhythmias, prolongation of the QTc interval on the electrocardiogram, sudden cardiac death, and structural changes in the heart such as left ventricular atrophy and cardiac fibrosis.

Patients with anorexia nervosa can have markedly slowed gastric emptying (Chapter 122), manifested by early satiety, nausea, abdominal pain, and bloating. Superior mesenteric artery syndrome, resulting in chronic intermittent or acute duodenal obstruction (which can be complete or partial), can result from the loss of fatty tissue that normally maintains the angle between the superior mesenteric artery and the aorta, thereby leading to extrinsic compression of the duodenum by the superior mesenteric artery. Normochromic, normocytic anemia and leukopenia are commonly observed owing to deficiencies in iron and vitamins as well as to gelatinous transformation of the bone marrow. Slight elevations of liver aminotransferase levels are common. Levels of thyroid-stimulating hormone and thyroxine may be slightly low, and levels of reverse triiodothyronine are usually elevated. Reduced bone density may auger the onset of premature osteopenia and osteoporosis.

ABSTRACT

The feeding and eating disorders encompass anorexia nervosa, bulimia nervosa, binge-eating disorder, avoidant/restrictive food intake disorder, pica, and rumination disorder. All are associated with significant impairments of physical health and psychosocial functioning. The neurobiology underlying these disorders is under study. Risk factors have been identified. The clinical manifestations of eating disorders are protean, can be caused directly or indirectly by the eating disorder, and can vary in severity to include potentially fatal outcomes. Cognitive behavioral therapy and interpersonal psychotherapy are most effective for bulimia nervosa and binge-eating disorder. Severely underweight patients with anorexia nervosa may require inpatient medical monitoring and supervised nutritional rehabilitation.

KEYWORDS

anorexia nervosa
bulimia nervosa
binge-eating disorder
avoidant/restrictive food intake disorder
psychotherapy
malnutrition
comorbid psychiatric disorders

Bulimia Nervosa

Bulimia nervosa frequently develops during late adolescence or early adulthood. Individuals with bulimia nervosa present with signs and symptoms most commonly associated with purging behavior. These problems include erosion of dental enamel owing to vomiting; gastrointestinal symptoms, including gastric acid reflux that can lead to dyspepsia and dysphagia; salivary gland hypertrophy; and potentially dangerous disturbances in electrolytes and in acid-base balance. For example, individuals who purge via self-induced vomiting may develop hypokalemic alkalosis.[6] Metabolic acidosis with the loss of bicarbonate from the bowel can occur in patients who are abusing laxatives as a result (Chapter 104).

Binge-Eating Disorder

Binge-eating disorder often manifests in adulthood, but adolescents also present with the disorder. The weights of individuals with binge-eating disorder are frequently in the overweight or obese range.[7] Compared with similar adults without binge-eating disorder, individuals with the disorder experience significant impairment in a number of domains of psychosocial functioning, including a poorer quality of life and more impaired functioning in their home and social lives. Individuals with binge-eating disorder often have higher levels of disability, health problems, and impairment of work productivity compared with similar individuals without binge eating.

The most common psychiatric comorbidities (Chapter 362) in binge-eating disorder are major depressive disorder, anxiety disorders, substance use disorders, and disruptive behavioral disorders. The presence of binge eating following bariatric surgery may impact the outcome (Chapter 201), thereby resulting in less weight loss or more weight regain.

Other Eating Disorders

Avoidant/restrictive food intake disorder, pica, and rumination disorder most frequently present during childhood but may also develop in adults. Individuals with avoidant/restrictive food intake disorder are at risk for a range of nutritional deficiencies that reflect the specific nature of their dietary disturbance.[8] When affected individuals are significantly underweight, they may develop physical complications similar to those seen in individuals with anorexia nervosa. Pica is sometimes associated with deficiencies in vitamins or minerals (e.g., zinc, iron) and, in youth, is often associated with intellectual disability. Pica can result in the development of serious medical complications, including poisoning, intestinal obstruction, and the formation of bezoars. As with pica, rumination disorder is often seen in children with intellectual disabilities. Extreme cases may be associated with emaciation.

DIAGNOSIS

Although a number of structured, well-validated assessments (e.g., www.EDA.org) exist for the diagnosis of eating disorders, eating disorders are typically diagnosed by review of the patient's history, symptoms, and behaviors in an interview format. Information should be gathered on interpersonal relationships, history of sexual and physical abuse, self-harm, and suicidal ideation or behavior. Family involvement is crucial, particularly for younger patients. A complete physical examination is recommended for all patients to assess body composition, vital signs, and cardiovascular function. Laboratory testing should include a complete blood count with differential and a platelet count, as well as blood chemistries (including electrolytes and tests of liver, renal, and thyroid function).

TREATMENT

The approach to the eating disorder shares some similarities, but syndrome-specific treatments vary.[9,10]

Anorexia Nervosa

The first goal of treatment for anorexia nervosa is to restore weight. For severely underweight patients, inpatient medical monitoring and supervised nutrition rehabilitation are required,[11] and higher calorie refeeding is superior to lower calorie refeeding acutely[A1] and at 1 year.[A2] For other patients, the optimal setting (inpatient vs. residential vs. outpatient treatment) is unclear,[A3] and consideration of the costs of the various options plays an important role in determining the choice of treatment. However, for pediatric patients, family-based psychotherapy, particularly during the early phases of the disorder, has demonstrated effectiveness.[A4] This treatment involves both joint family sessions and simultaneous, but independent, patient/family intervention. Antidepressants (e.g., selective serotonin reuptake inhibitors) have not been found to be effective, but the atypical antipsychotic olanzapine (2.5 to 10 mg/d) has been associated with a modest increase in weight gain.[A5] The treatment potential of neuromodulative techniques such as transcranial direct current stimulation, repetitive transcranial magnetic stimulation, and deep brain stimulation are currently being explored. Results with cannabinoids as an appetite stimulant have been inconclusive.[A6]

Bulimia Nervosa

Cognitive-behavioral therapy is the treatment of choice for bulimia nervosa. Interpersonal psychotherapy is also effective, particularly for patients who are nonresponsive to cognitive-behavioral therapy.[12] Antidepressants, especially selective serotonin reuptake inhibitors (Chapter 362), are modestly effective for reducing binge eating in bulimia nervosa over the short term and long term, and fluoxetine (60 mg/day) is approved by the U.S. Food and Drug Administration (FDA) for this purpose.[13] Topiramate (25 to 400 mg/day) has consistently been shown to decrease binge eating in bulimia nervosa, but cognitive side effects limit its usefulness.

Binge-Eating Disorder

Psychological treatment for binge-eating disorder aims to reduce binge eating, reduce concerns about body weight and shape, and prevent excess weight gain and/or induce modest weight loss. Cognitive-behavioral therapy, interpersonal psychotherapy, and behavioral weight loss are first-line treatments, but cognitive-behavioral therapy–guided self-help approaches are also useful, especially when specialist care is not available. However, face-to-face cognitive-behavioral therapy leads to quicker and greater reductions in the number of objective binge-eating episode days, better abstinence rates, and better eating disorder psychopathologic findings and may be generally a better initial treatment option than Internet-based guided self-help.[A7] Lisdexamfetamine (50 or 70 mg/day), which can reduce binge-eating episodes and is associated with modest weight loss, is currently the only FDA-approved medication for binge-eating disorder in adults.[A8] Selective serotonin reuptake inhibitors (e.g., fluoxetine 60 mg/day) and topiramate (25 to 400 mg/day) can also reduce the frequency of binge eating relative to placebo in short-term trials, but topiramate is frequently associated with cognitive side effects.

Avoidant/Restrictive Food Intake Disorder, Pica, and Rumination Disorder

Few controlled trials have evaluated treatments for avoidant/restrictive food intake disorder, pica, and rumination disorder. Current approaches are based on behavioral interventions.[14–16] Weight restoration is indicated for underweight individuals.

PREVENTION

The U.S. Preventive Services Task Force found insufficient data[A9] to recommend for or against screening adolescents and adults who are not known to be at high risk for eating disorders,[17] but some professional societies recommend such screening as part of a comprehensive evaluation.[18] Currently available data indicate that interactive, multisession programs with adolescent girls are more effective than universal, didactic, heterogeneous programs for reducing the risk factors that are associated with eating disorders. For example, dissonance-based programs, in which participants are encouraged to challenge the notion that being thinner will lead to being happier, aimed at reducing risk factors for eating disorder in adolescent girls have demonstrated effectiveness, especially for reducing binge eating.

PROGNOSIS

Eating disorders tend to exhibit a remitting and relapsing natural course across the lifespan and with high rates of diagnostic crossover. Outcome data indicate that patients with anorexia nervosa tend to transition to bulimia nervosa or an unspecified eating disorder, whereas patients with bulimia nervosa and binge-eating disorder may migrate from one to the other.

Anorexia Nervosa

The outcome of anorexia nervosa is extremely variable. Many individuals, especially those with brief mild illnesses, completely remit with resolution of signs, symptoms, and at least some of the associated psychological issues. Conversely, anorexia nervosa has one of the highest mortality rates among all psychiatric diagnoses due to suicide, nutritional deficits, cardiac complications, and substance abuse. Between these extremes, most individuals may remain chronically underweight or gain weight and develop bulimia nervosa.

Bulimia Nervosa

Most individuals with bulimia nervosa (70% or greater) who receive treatment fully remit when assessed 5 to 20 years later, but remission rates are much lower (27 to 28%) at 1-year follow-up. If individuals with bulimia nervosa do not achieve remission within 5 years, however, they are likely to exhibit a chronic course. Diagnostic crossover from bulimia nervosa to anorexia nervosa is relatively rare. However, the more frequent diagnostic crossover between bulimia nervosa and binge-eating disorder suggests possible common psychological and/or biological processes.

Other Eating Disorders

A paucity of data exists on the long-term outcomes for binge-eating disorder patients, but upward of 80% of patients may remit at 1 year following outpatient treatment. Little information is currently available on the long-term course of avoidant/restrictive food intake disorder, pica, and rumination disorder.

201 OBESITY

MICHAEL D. JENSEN AND DANIEL H. BESSESEN

Obesity is the most common nutritional disorder in the United States, and it directly or indirectly accounts for a significant portion of health-related expenses. Lifestyle change, antiobesity medications, and bariatric surgery are evidence-based treatment options, but each requires training and time to implement.

DEFINITION

Obesity, which is a degree of excess adiposity that can predispose to adverse health consequences, is a disease of body weight regulation, much as diabetes is a disease of glucose regulation.[1] Body mass index (BMI), calculated as weight in kilograms divided by height squared in meters, is the most commonly used screening tool to assess the health risks related to weight.

EPIDEMIOLOGY

More than 1.9 billion adults worldwide are overweight, and over 650 million are obese.[2] Obesity causes an estimated 4.7 million deaths worldwide. In the United States, over 70% of adults are overweight, and the prevalence of obesity is about 42% in women and 44% in men.[3] BMI rises between ages 20 and 60 years and falls slightly thereafter.[4] Severe obesity is inversely associated with urbanization,[5] with a significantly greater prevalence of obesity and severe obesity among adults living in nonmetropolitan areas compared with large metropolitan statistical areas.[6] Black American women and Mexican Americans of both sexes have the highest rates of overweight and obesity in the United States. Women in lower socioeconomic classes are much more likely than those in higher socioeconomic classes to be obese, an association that reduces, but does not eliminate, the racial differences in the prevalence of obesity. Whether the remaining racial differences in the prevalence of obesity are due to genetic, constitutional, or social and environmental factors is not yet known.

The health risks associated with increased adiposity increase continuously as BMI exceeds 25 (Table 201-1). Lower BMI values of 23 to 24 are recommended for Asian populations, who are at risk for the typical metabolic complications of obesity at lower BMI and waist circumferences than are individuals of other ethnicities. Risks associated with being overweight are modest but are higher in the presence of central obesity. Some persons who are overweight (BMI of 25.0 to 29.9) may have increased muscle mass rather than increased body fat; these individuals are not difficult to identify clinically and do not have an elevated waist circumference. The prevalence of comorbid conditions and risk of new morbid conditions increase considerably at a BMI of more than 30, which is the definition of obesity. Obesity is divided into three classes, also depending on BMI (see Table 201-1).

Young adults, who accumulate greater exposure to metabolic and mechanical damage from being overweight or obese throughout their lives, are at increased risk for chronic health conditions such as coronary heart disease and type 2 diabetes mellitus. By comparison, the increase in mean BMI with age, though deleterious, is not as much of a threat to population health as is a similar increase in the BMI of younger populations.

The lowest mortality rates for young adults have historically been for a BMI in the normal range (20.0 to 24.9), whereas the BMI associated with the lowest mortality rates is somewhat above 25 kg/m^2 for adults in their 60s and 70s.[7] Data also suggest that the optimal BMI may be about 27.0 for older adults given current life expectancy data.

PATHOBIOLOGY

Genetic and constitutional susceptibility to obesity are heavily influenced by the environment. Studies of twins adopted into different families indicate that within a given environment, a significant portion of the variation in weight is genetic. However, the growing prevalence of obesity is related to changes in environment, not human genetics.

Genetic Aspects of Human Obesity

Variants in the fat mass and obesity-associated (FTO) gene, which are relatively common (16% of adults are homozygous for the predisposing allele), account for only a few percent of the differences in body weight. Large genome-wide association studies have identified over 100 loci that associate with BMI, but together these genes account for less than 3% of the variance in BMI. The majority of the genes associated with BMI are expressed in the central nervous system, thereby suggesting effects on ingestive behavior. Genome-wide association studies have also identified about 50 loci that are associated with waist-to-hip ratio after adjusting for BMI, but these loci combined account for only 1 to 2% of the variance in waist-to-hip ratio. Most of these genes are preferentially expressed in adipose tissue, thereby implying that hereditary differences in body fat distribution are driven by genetic factors.

Genetic obesity is seen in a variety of childhood-onset conditions, including autosomal dominant Prader-Willi (Chapter 214) and Albright hereditary osteodystrophy, as well as autosomal recessive Laurence-Moon-Biedl, Cohen, Carpenter, Alstrom, and Tubby syndromes. Virtually all monogenic obesity syndromes cause hyperphagia by disrupting parts of appetite regulation pathways. For example, children with homozygous or compound heterozygous loss-of-function mutations in the genes encoding leptin (LEP) and the leptin receptor (LEPR) develop intense hyperphagia that results in severe obesity. Congenital leptin deficiency results in undetectable serum leptin concentrations, whereas leptin concentrations are not unusually increased

TABLE 201-1 CLASSIFICATION OF OVERWEIGHT AND OBESITY BY BODY MASS INDEX (BMI)

	OBESITY CLASS	BMI (kg/m^2)
Underweight		<18.5
Normal		18.5-24.9
Overweight		25.0-29.9
Obesity	I	30.0-34.9
Obesity	II	35.0-39.9
Extreme obesity	III	≥40

Other Eating Disorders

A paucity of data exists on the long-term outcomes for binge-eating disorder patients, but upward of 80% of patients may remit at 1 year following outpatient treatment. Little information is currently available on the long-term course of avoidant/restrictive food intake disorder, pica, and rumination disorder.

201 OBESITY

MICHAEL D. JENSEN AND DANIEL H. BESSESEN

Obesity is the most common nutritional disorder in the United States, and it directly or indirectly accounts for a significant portion of health-related expenses. Lifestyle change, antiobesity medications, and bariatric surgery are evidence-based treatment options, but each requires training and time to implement.

DEFINITION

Obesity, which is a degree of excess adiposity that can predispose to adverse health consequences, is a disease of body weight regulation, much as diabetes is a disease of glucose regulation.[1] Body mass index (BMI), calculated as weight in kilograms divided by height squared in meters, is the most commonly used screening tool to assess the health risks related to weight.

EPIDEMIOLOGY

More than 1.9 billion adults worldwide are overweight, and over 650 million are obese.[2] Obesity causes an estimated 4.7 million deaths worldwide. In the United States, over 70% of adults are overweight, and the prevalence of obesity is about 42% in women and 44% in men.[3] BMI rises between ages 20 and 60 years and falls slightly thereafter.[4] Severe obesity is inversely associated with urbanization,[5] with a significantly greater prevalence of obesity and severe obesity among adults living in nonmetropolitan areas compared with large metropolitan statistical areas.[6] Black American women and Mexican Americans of both sexes have the highest rates of overweight and obesity in the United States. Women in lower socioeconomic classes are much more likely than those in higher socioeconomic classes to be obese, an association that reduces, but does not eliminate, the racial differences in the prevalence of obesity. Whether the remaining racial differences in the prevalence of obesity are due to genetic, constitutional, or social and environmental factors is not yet known.

The health risks associated with increased adiposity increase continuously as BMI exceeds 25 (Table 201-1). Lower BMI values of 23 to 24 are recommended for Asian populations, who are at risk for the typical metabolic complications of obesity at lower BMI and waist circumferences than are individuals of other ethnicities. Risks associated with being overweight are modest but are higher in the presence of central obesity. Some persons who are overweight (BMI of 25.0 to 29.9) may have increased muscle mass rather than increased body fat; these individuals are not difficult to identify clinically and do not have an elevated waist circumference. The prevalence of comorbid conditions and risk of new morbid conditions increase considerably at a BMI of more than 30, which is the definition of obesity. Obesity is divided into three classes, also depending on BMI (see Table 201-1).

Young adults, who accumulate greater exposure to metabolic and mechanical damage from being overweight or obese throughout their lives, are at increased risk for chronic health conditions such as coronary heart disease and type 2 diabetes mellitus. By comparison, the increase in mean BMI with age, though deleterious, is not as much of a threat to population health as is a similar increase in the BMI of younger populations.

The lowest mortality rates for young adults have historically been for a BMI in the normal range (20.0 to 24.9), whereas the BMI associated with the lowest mortality rates is somewhat above 25 kg/m^2 for adults in their 60s and 70s.[7] Data also suggest that the optimal BMI may be about 27.0 for older adults given current life expectancy data.

PATHOBIOLOGY

Genetic and constitutional susceptibility to obesity are heavily influenced by the environment. Studies of twins adopted into different families indicate that within a given environment, a significant portion of the variation in weight is genetic. However, the growing prevalence of obesity is related to changes in environment, not human genetics.

Genetic Aspects of Human Obesity

Variants in the fat mass and obesity-associated (FTO) gene, which are relatively common (16% of adults are homozygous for the predisposing allele), account for only a few percent of the differences in body weight. Large genome-wide association studies have identified over 100 loci that associate with BMI, but together these genes account for less than 3% of the variance in BMI. The majority of the genes associated with BMI are expressed in the central nervous system, thereby suggesting effects on ingestive behavior. Genome-wide association studies have also identified about 50 loci that are associated with waist-to-hip ratio after adjusting for BMI, but these loci combined account for only 1 to 2% of the variance in waist-to-hip ratio. Most of these genes are preferentially expressed in adipose tissue, thereby implying that hereditary differences in body fat distribution are driven by genetic factors.

Genetic obesity is seen in a variety of childhood-onset conditions, including autosomal dominant Prader-Willi (Chapter 214) and Albright hereditary osteodystrophy, as well as autosomal recessive Laurence-Moon-Biedl, Cohen, Carpenter, Alstrom, and Tubby syndromes. Virtually all monogenic obesity syndromes cause hyperphagia by disrupting parts of appetite regulation pathways. For example, children with homozygous or compound heterozygous loss-of-function mutations in the genes encoding leptin (LEP) and the leptin receptor (LEPR) develop intense hyperphagia that results in severe obesity. Congenital leptin deficiency results in undetectable serum leptin concentrations, whereas leptin concentrations are not unusually increased

ABSTRACT

The epidemiology and biology of obesity are best understood as they relate to energy expenditure, the regulation of appetite, and their medical/mechanical complications. The primary treatments of obesity include dietary intervention, increased physical activity, and behavioral modalities. Antiobesity medications, endoscopic treatments, and bariatric surgery are indicated for difficult-to-treat cases.

in those with LEPR deficiency. Approximately 5% of patients with severe, early-onset obesity have been reported to have heterozygous loss-of-function MC4R mutations, which appear to be inherited in a codominant manner. The features of MC4R deficiency include hyperphagia, hyperinsulinemia, and increased linear growth. Homozygous or compound heterozygous mutations in proopiomelanocortin (POMC) can result in hyperphagia and early-onset obesity, isolated adrenocorticotropic hormone (ACTH) deficiency (due to lack of adrenocorticotrophin), and hypopigmentation of skin and hair (due to lack of signaling through the melanocortin 1 receptor). Humans lacking prohormone convertase 1 also develop severe, early-onset obesity and ACTH deficiency due to impaired processing of POMC.

Constitutional Influences on Obesity

Environmental factors can result in long-term, epigenetic effects that affect body weight regulation and the susceptibility to obesity-related health problems. For example, undernutrition in the last trimester of pregnancy and in the early postnatal period decreases the risk of adult obesity, although the low birthweight associated with undernutrition (or smoking) in late pregnancy also increases the risk of adulthood hypertension, abnormal glucose tolerance, and cardiovascular disease. In contrast, undernutrition limited to the first two trimesters of pregnancy is associated with an increased probability of adult obesity. Infants of diabetic mothers tend to be fatter than those of nondiabetic mothers, and children of diabetic mothers have a greater prevalence of obesity when they are 5 to 19 years old, independent of whether their mother is obese. Finally, intrauterine exposure to the diabetic environment results in an increased risk of diabetes mellitus and obesity in the offspring.

Environmental Contributors to Obesity

Dramatic changes in the environment of developed and even developing countries over the past 50 years include reduced demands for physical activity and alterations in the food supply (Table 201-2). These changes in the food supply help explain why the reduced energy expenditures by persons in the industrial and postindustrial eras have not been accompanied by a decrease in energy intake.

Food

The consumption of energy-dense foods results in greater energy intake because adults tend to respond to food volume rather than to the energy content. Many high-fat foods are also energy dense and contribute to weight gain. The consumption of sugar-sweetened beverages, such as soft drinks and fruit juices, is not accompanied by a decrease in food intake to offset the extra energy intake and promotes weight gain. The larger portion size of food and beverages also increases food intake. Food variety can also affect energy intake, and the ready availability of an increased variety of entrees, sweets, snacks, and carbohydrates is associated with an increase in food intake and body fatness. In contrast, an increase in the variety of vegetables available does not appear to increase energy intake and is not associated with increased body fatness. Other factors include the reduced costs of food, increased availability, and palatability. Psychological factors such as dietary restraint or disinhibition, as well as the social context in which the food is present, can influence how food properties affect energy intake.

Physical Activity

Physical activity (Chapter 14) levels have been decreasing in the United States and worldwide, as reduced activity at work is not replaced, on average, by increased leisure activity. The result is decreased energy expenditure, estimated to be over 100 calories/day, at a time when the food supply has led to sustained or increased caloric consumption. The amount of time spent in sedentary pursuits is associated with an increased risk of overweight and obesity, likely independent of participation in traditional exercise activities.

Regulation of Body Weight and Energy Balance

The typical U.S. adult will take in and expend approximately 2000 to 3000 kcal/day. Consistent errors of even 1% in excess food consumption can result in body fat gain of 25 to 30 pounds in 10 years, assuming no change in energy expenditure, so adults who do not gain weight must regulate their average energy balance with greater than 1% precision. This balanced regulation of energy intake and energy expenditure requires both conscious and unconscious processes.

The excess energy consumed by adults is generally stored as triglycerides in adipocytes. Humans continuously recruit new adipocytes from a large preadipocyte pool to replace dying adipocytes. Although the primary means by which abdominal adipose tissue mass expands is by increasing the size of existing fat cells (adipocyte hypertrophy), this process can store only a limited amount of fat. Adults who gain leg fat accumulate more rather than larger adipocytes on average, thereby resulting in a net increase in the number of adipocytes. Some adults recruit new adipocytes more readily than others, and their body fat is more related to adipocyte hyperplasia (increased fat cell number) than adipocyte hypertrophy. Adults who gain fat primarily via adipocyte hypertrophy are more likely to be insulin resistant.

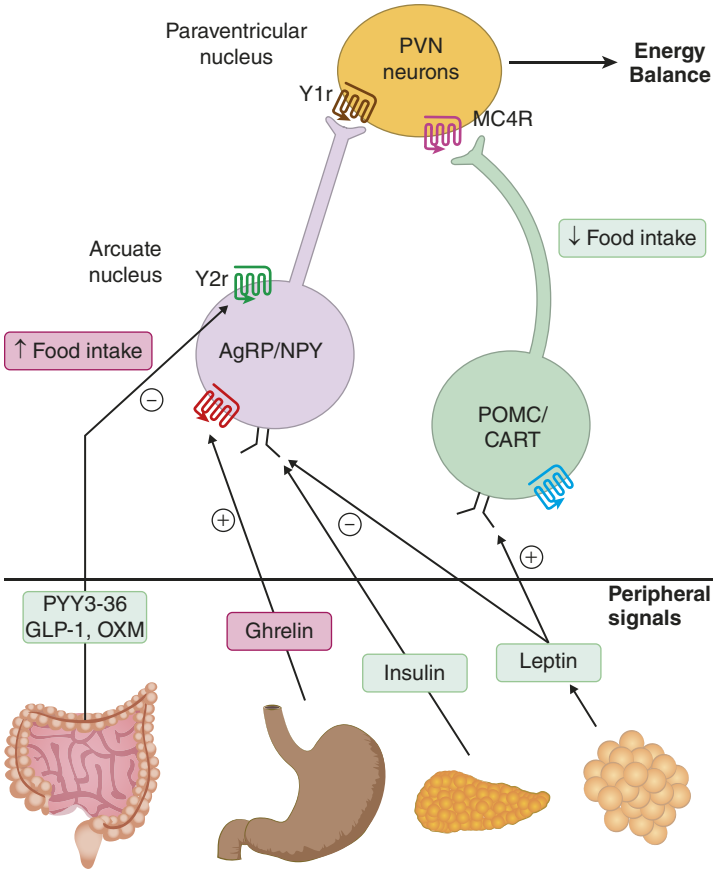
In addition to its role in storing excess energy as triglyceride, adipose tissue secretes a large number of hormones (termed adipokines), the most prominent of which is leptin. Leptin has a role in regulating appetite, and very low leptin concentrations result in increased hunger. The other well-known adipokine is adiponectin, which is thought to have metabolic protective properties. The functions of scores of other adipokines have not yet been clearly identified in humans.

Energy Intake

Signals can affect hunger, which is the compelling need or desire for food; satiation, which is the state of being satisfactorily full and unable to consume more; and satiety, which is the sense of no longer being hungry. The hypothalamus is a key component of the regulation of the intake of food (E-Fig. 201-1). Hypothalamic arcuate nucleus neurons synthesize neuropeptide Y (NPY) and agouti-related protein (AgRP) and are activated under energy-deficit conditions by reduced levels of insulin and leptin, thereby resulting in the drive to eat (orexigenic response). When energy intake is sufficient, POMC neurons in the arcuate nucleus generate responses that reduce appetite (anorectic responses). The neurons that express POMC also express cocaine- and amphetamine-related transcript (CART). POMC is processed to the melanocortin (MSH) peptides alpha, beta, and gamma MSH, which are melanocortin 3 and 4 receptor (MC4R) agonists. These arcuate nucleus neurons project to MC4R-expressing neurons in the paraventricular nucleus, where activation of MC4R generates the anorectic response. In conditions of energy deficit, the MC4R receptor is inhibited by AgRP. Neurons in the paraventricular nucleus also express NPY receptors, which, when activated, cause hunger. The balance among these numerous signals plays an important role in the desire to eat. Perhaps the most obvious example of how this pathway can be disrupted is the increase in hunger in response to high-dose, exogenous corticosteroids; suppression of POMC neurons by corticosteroids results in unopposed activity of NPY on paraventricular nucleus neurons.

Satiety, which is the sense of no longer being hungry, is a complex set of postprandial events that affect the interval to and/or the amount consumed at the next meal. The leptin receptor is highly expressed in the hypothalamus. When it is activated by leptin, which is secreted by adipocytes, the expression of POMC increases, thereby leading to reduced food intake. Gut peptides that can influence food intake are secreted in response to mechanical stimuli (e.g., the fullness of the stomach) and/or the presence of nutrients in the jejunum and ileum. These peptides include peptide YY 36 (PYY), glucagon-like peptide 1 (GLP-1), and oxyntomodulin (OXM) that, like leptin and insulin, inhibit neurons that express NPY and AgRP. In contrast, ghrelin activates NPY and AgRP neurons, thereby generating a sensation of hunger, an effect that is exacerbated by prolonged fasting, possibly because leptin secretion decreases out of proportion to the loss of body fat.

In addition to the hypothalamic energy balance system, other central nervous system responses have important effects on food intake (E-Table 201-1).



E-FIGURE 201-1. Central appetite regulation pathways. AgRP = agouti-related protein; CART = cocaine- and amphetamine-related transcript; GLP-1 = glucagon-like peptide 1; MC4R = melanocortin 4 receptor; NPY = neuropeptide Y; OXM = oxyntomodulin; POMC = proopiomelanocortin; PVN = paraventricular nucleus; PYY3-36 = peptide tyrosine tyrosine 3-36.

E-TABLE 201-1 CENTRAL NERVOUS SYSTEM REGULATION OF APPETITE

Brain region	Functions	Neurotransmitters
Hypothalamus	Energy homeostasis	Norepinephrine, GABA, POMC, CART, AgRP, NPY
Ventral striatum	Reward aspects of food intake	Dopamine
Prefrontal cortex	Executive function, impulse control	Norepinephrine, dopamine, glutamate
Brainstem, vagus nerve	Signals from GI tract	GLP-1
Cortex	Social meaning of eating	

AgRP = agouti-related protein; CART = cocaine- and amphetamine-related transcript; GABA = γ-aminobutyric acid; GI = gastrointestinal; GLP-1 = glucagon-like peptide 1; NPY = neuropeptide Y; POMC = proopiomelanocortin.

Relevant structures include the ventral striatum, where the reward aspects of food intake are determined; the prefrontal cortex, where executive function and impulse control take place; the brain stem, where vagal inputs from the gastrointestinal tract modulate food intake; and the cortex, where the social meaning of eating is interpreted. Other factors that have been shown to affect food intake include cholecystokinin, which causes satiation but has no effect on satiety, and pancreas-derived amylin, which acts on the gastrointestinal tract and the hypothalamus to inhibit appetite.

Signals of energy availability from the small intestine, stomach, pancreas, and adipose tissue are relayed to the hypothalamus via the circulation. In the arcuate nucleus of the hypothalamus, neurons that express NPY and AgRP are activated under energy deficit conditions and drive feeding (orexigenic) responses by signaling to NPY1 receptor (Y1r) neurons in the paraventricular nucleus (PVN). Ghrelin activates NPY and AgRP neurons, whereas PYY, GLP-1, OXM, insulin, and leptin inhibit these neurons. In the arcuate nucleus of the hypothalamus, neurons that express POMC generate anorectic signals under conditions of energy surplus. POMC neurons coexpress CART. Anorectic peptides (PYY, GLP-1, and OXM) activate POMC neurons. In the paraventricular nucleus, melanocortin melanocyte-stimulating hormone (α-MSH), which is a product of POMC cleavage, activates the MC4R, which generates a feeling of satiety. Depending on energy needs versus availability, the balance between activating NPY/AgRP as compared with POMC/CART neurons is thought to drive hunger and satiety.

Energy Expenditure

Daily energy expenditures in adults can range from less than 1400 kcal/day to more than 5000 kcal/day, with larger, more physically active individuals having the greatest energy needs. Typically, daily energy expenditure is divided into resting (or basal) metabolic rate, the thermic effect of food, and physical activity energy expenditure.

Basal Metabolic Rate

The basal metabolic rate (BMR) is the energy expenditure of lying still, at rest, awake, and in the fasting state. Most formulas calculate BMR as strictly measured, and BMR is considered the foundation of daily energy expenditure. Under most clinical circumstances, however, the resting metabolic rate (RMR) is measured because of the difficulty in measuring BMR; RMR is not necessarily measured before arising from bed and may not be in the fasting state, so it may be greater than BMR. For most sedentary adult Americans, BMR represents the major portion of energy expended during the day and may range from less than 1200 to more than 3000 kcal/day. Most (~80%) of the variability in BMR can be explained by the amount of lean and fat tissue. In addition, BMR is slightly lower in women than in men and in older than in younger adults even after accounting for the amount of lean and fat tissue. Heritable factors may account for as much as 10% of the interindividual differences in BMR. With an energy-restricted diet, BMR may decline out of proportion to the loss of fat-free mass. Reductions in the production of triiodothyronine from thyroxine and the sympathetic nervous system drive are thought to contribute to this phenomenon. Likewise, during brief periods of overfeeding, BMR increases slightly above that which would be expected for the amount of lean tissue present. Formulas to estimate BMR (available through numerous online calculators: https://www.calculators.org/health/bmr.php.) on the basis of height, weight, age, and sex are accurate to within 10% in approximately 90% of adults with BMIs of 18.5 to 45 kg/m^2.

Muscle accounts for only 25% of BMR but can account for 80 to 90% of energy expenditure during exercise. Adipose tissue requires only about 3 kcal/kg of body fat per day, so it is a minor contributor to daily energy expenditure.

Brown fat is adipose tissue that expresses large amounts of uncoupling protein-1 (a protein that allows a mitochondrial membrane proton leak).[8] When activated, this process results in the release of heat as opposed to chemical work from adenosine triphosphate—"uncoupling" of substrate oxidation from chemical or mechanical work. This thermogenic tissue, which exists only in small amounts in adults, might become a target for future interventions to reduce adiposity. Methods used to detect brown fat largely rely on ^{18}F-fluorodeoxyglucose positron emission tomography scanning of humans exposed to cold.

Physical Activity Energy Expenditure

The energy expenditure of physical activity is a product of the amount of work done and the work efficiency of the individual. Work units are expressed as metabolic equivalents (METs; see Table 14-1), a multiple of the RMR. If an individual's RMR is 1 kcal/minute (1440 kcal/day), a workload of 5 METs would be 5 kcal/minute. Although most sedentary individuals can work for only a limited amount of time at relatively low workloads, highly trained athletes can work at extremely high METs (>16) for extended periods.

Nonexercise activity thermogenesis is the energy expense of performing all activities other than exercise- or employment-related activity. Such activities may include tasks as mundane as getting up to walk 50 feet to the water fountain or spending 8 hours cleaning one's living space. The range of observed nonexercise activity thermogenesis varies from less than 100 to more than 800 kcal/day. On average, about 10% of the energy content of food (ranging from a low of about 3% to a high of about 15%) is expended in the process of digestion, absorption, and metabolism of nutrients. The energy expended from a physically demanding job or volitional exercise may or may not be offset by reductions in spontaneous (nonemployment) activity.

Secondary Causes of Obesity

A number of medications cause weight gain in some or most of the patients for whom they are prescribed (Table 201-3). Awareness of the medications that have this potential can facilitate weight loss treatment in some patients.

Less than 1% of obese patients have an underlying systemic disease that can explain the development of their obesity. Endocrinopathies, which are the most common secondary cause of obesity, include Cushing syndrome (Chapter 208), hypothalamic damage that results in overeating (most commonly after pituitary surgery), insulinoma (Chapter 211), and hypothyroidism (Chapter 207). With hypothyroidism, the weight gain is largely due to fluid retention rather than to the accumulation of fat.

Sexual, physical (Chapter 223), and emotional abuse, especially in women, can result in long-term adverse consequences, including obesity. Abused women may be severely obese, suffer from chronic depression, and experience a number of psychosomatic symptoms, particularly chronic gastrointestinal distress. Identifying these issues before initiating weight loss programs is important because successful weight loss may actually aggravate the distress experienced by these women.

Metabolic Complications of Obesity

A central or upper body fat distribution is more predictive than total fat mass of the metabolic complications of obesity. The release of free fatty acids and glycerol from adipose tissue into the circulation by lipolysis provides 50 to 100% of daily energy needs. Adipose tissue lipolysis is regulated primarily by insulin (inhibition) and catecholamines (stimulation), although growth hormone, cortisol, and atrial natriuretic peptide also stimulate lipolysis. Upper body obesity is associated with a higher postprandial release of free fatty acids, and this abnormality is particularly evident in type 2 diabetes.

Insulin Resistance

Insulin resistance (Chapter 210) refers to a diminished ability of insulin to promote glucose uptake and to inhibit the release of glucose into the circulation. Skeletal muscle is the primary site of insulin-stimulated glucose uptake, oxidation, and storage, whereas the liver is the primary site of glucose production. Insulin resistance initially leads to hyperinsulinemia and may eventually lead to the development of type 2 diabetes if β-cells become exhausted (Chapter 210), although many obese individuals with insulin resistance do not develop diabetes.

The ability of insulin to promote glucose uptake, oxidation, and storage in muscle and to suppress plasma free fatty acid concentrations is reduced in upper body obesity. High plasma free fatty acid concentrations can induce a state of insulin resistance both in the muscle (glucose uptake) and in the liver (glucose release), independent of obesity (Chapter 210).

Hypertension

In obesity, increased circulating blood volume, abnormal vasoconstriction, decreased vascular relaxation, and increased cardiac output may all contribute to hypertension (Chapter 64). The effect of hyperinsulinemia to increase renal sodium absorption may contribute to hypertension through increased circulating blood volume. Abnormalities of vascular resistance also contribute to the pathophysiologic process of obesity-related hypertension. Some obese adults have increased sympathetic nervous system activity, which could contribute to obesity-associated hypertension. Finally, angiotensinogen (also produced by adipocytes) is a precursor of the vasoconstrictor angiotensin II and is proposed to contribute to elevated blood pressure.

TABLE 201-3 PHARMACOLOGIC INFLUENCES ON WEIGHT GAIN AND ALTERNATIVE THERAPIES

DRUGS THAT MAY PROMOTE WEIGHT GAIN	ALTERNATIVE TREATMENTS: WEIGHT NEUTRAL OR WEIGHT LOSS
PSYCHIATRIC AND NEUROLOGIC MEDICATIONS Antipsychotics: olanzapine, clozapine, risperidone, quetiapine, aripiprazole Antidepressants Tricyclics: imipramine, amitriptyline Triazolopyridines: trazodone Serotonin reuptake inhibitors: paroxetine, fluoxetine, citalopram Tetracyclics: mirtazapine Monoamine oxidase inhibitors Antiepileptic drugs: gabapentin (higher doses), valproic acid, carbamazepine, divalproex Mood stabilizers: lithium, carbamazepine, lamotrigine, gabapentin (higher doses)	**ALTERNATIVE PSYCHIATRIC AND NEUROLOGIC MEDICATIONS** Ziprasidone Nortriptyline, bupropion, nefazodone, fluvoxamine, sertraline, duloxetine Topiramate, zonisamide (weight loss), lamotrigine (less weight gain)
STEROID HORMONES Progestational steroids Corticosteroids Hormonal contraceptives	**ALTERNATIVES TO STEROID HORMONES** Barrier methods, intrauterine device Nonsteroidal anti-inflammatory drugs
ANTIDIABETES AGENTS Insulin (most forms) Sulfonylureas Thiazolidinediones	**ALTERNATIVE ANTIDIABETES AGENTS** Metformin Acarbose, miglitol Exenatide Dipeptidyl peptidase 4 inhibitors Liraglutide Sodium-glucose cotransporter 2 inhibitors
ANTIHISTAMINES Commonly reported with older agents; also oxatomide, loratadine, and azelastine	**ALTERNATIVES TO ANTIHISTAMINES** Decongestants, mast cell stabilizers, antagonists of endogenous mediators of inflammation
ANTIHYPERTENSIVE AGENTS α-Adrenergic and β-adrenergic receptor blockers Calcium channel blockers: nisoldipine	**ALTERNATIVE ANTIHYPERTENSIVE AGENTS** Angiotensin-converting enzyme inhibitors Angiotensin receptor blockers Calcium channel blockers: most other agents Diuretics
HIGHLY ACTIVE ANTIRETROVIRAL THERAPY	

Dyslipidemia

Upper body obesity and type 2 diabetes mellitus are associated with increased concentrations of triglycerides, decreased concentrations of high-density lipoprotein (HDL) cholesterol, and a high proportion of small, low-density lipoprotein (LDL) particles (Chapter 190). This dyslipidemia contributes to the increased cardiovascular risk observed in metabolic syndrome. Fasting hypertriglyceridemia is caused by increased hepatic very low density lipoprotein (VLDL) secretion, which may be driven by increased delivery of free fatty acids to the liver from both visceral fat and upper body subcutaneous fat. The reduced HDL cholesterol concentrations and the increased small, dense LDL particle concentrations associated with upper body obesity are likely an indirect consequence of elevated triglyceride-rich VLDL. Genetic influences play a significant role in the expression of these lipid abnormalities. Polymorphisms in the genes for apolipoprotein E, lipoprotein lipase, apolipoprotein B-100, and apolipoprotein A-II are correlated with increased triglycerides and decreased HDL.

Endocrine Manifestations of Obesity

Obesity is associated with abnormalities of the endocrine system, including polycystic ovary syndrome (Chapter 218), which is characterized by mild hirsutism and irregular menses or amenorrhea with anovulatory cycles. The insulin resistance associated with obesity may trigger the development of polycystic ovary syndrome in susceptible individuals. Obese men may suffer from mild to severe hypothalamic hypogonadism (Chapter 216), which improves with weight loss.

Systemic Complications of Obesity

The excess body weight associated with obesity is thought to be responsible for the increased prevalence of lower extremity degenerative joint disease (Chapter 241). Severely obese individuals may also have problems with venous stasis (Chapter 68), which is occasionally aggravated by right-sided heart failure.

Sleep apnea (Chapter 374) is common in severely obese patients and is more prevalent in men and in women with an upper body/visceral obesity. Sleep apnea is most likely explained by enlargement of upper airway soft tissue, resulting in collapse of the upper airways during inspiration while sleeping. The obstruction leads to apneas, with hypoxemia, hypercarbia, and high levels of catecholamines and endothelins. The frequent arousals to restore breathing result in poor sleep quality. Sleep apnea is associated with an increased risk of hypertension, and if sleep apnea is severe, it can lead to right-sided heart failure and sudden death.

Obesity is associated with an increased risk of at least 13 different types of cancer (breast, esophageal, liver, gallbladder, stomach, pancreas, colorectal, ovarian, uterine, renal cell, thyroid, meningioma, and multiple myeloma),[9] likely due to higher levels of insulin-like growth factor and estrogens. Obese individuals have a greater prevalence of gastroesophageal reflux disease (Chapter 124) and gallstones (Chapter 141). Fatty liver and nonalcoholic steatohepatitis (Chapter 138) are strongly associated with overweight, obesity, and the metabolic syndrome.

DIAGNOSIS

Evaluation of Obesity

In the office practice, obtaining height and weight allows calculation of BMI. (https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmicalc.htm). A review of the patient's lifestyle, including an assessment of physical activity level (Chapter 14) and eating habits (Chapter 13), may help provide information about why the patient is obese. A family history of obesity, or long-standing obesity, provides evidence against a secondary cause of obesity. A careful medication history, including over-the-counter medications, and social history may help the clinician identify precipitating factors that can be modified.

For patients with a BMI above 25 and below 35, measuring waist circumference is recommended to help with the treatment decision-making process. In persons of European and African descent, waist circumference cut points of more than 102 cm (40 inches) for men and more than 88 cm (35 inches) for women are indicators of increased metabolic risk. Adults with waist circumferences above the cut points deserve further evaluation to detect other cardiovascular disease risk factors. Adults with class II or class III obesity are at sufficiently high risk that waist circumference information does not add valuable information.

Blood pressure should be measured, with a large blood pressure cuff, if needed. A suspicion for sleep apnea should prompt a referral for an overnight sleep test (Chapter 374).

Routine blood testing for persons with a BMI 25 to 35 kg/m^2 and an elevated waist circumference should include a fasting glucose concentration and a lipid panel. Other laboratory tests (thyroid and liver function studies) may be indicated if symptoms or signs warrant.

TREATMENT

General Considerations

Before a patient enters a weight management program, the clinician should try to ensure that the patient is interested and ready to make lifestyle changes and has realistic goals and expectations. Patients who expect to lose large amounts of weight in a short time are virtually doomed to disappointment. Medical treatment programs, even if they include pharmacotherapy, struggle to achieve a sustained weight loss of more than 10%. Although this amount of weight loss is sufficient to markedly reduce the medical complications of obesity, disappointment with "only" 10% weight loss may cause patients to abandon a medically successful program. Helping the patient to accept that lifestyle changes resulting in achievable (10%) weight loss is a reasonable, initial goal can be challenging for a physician.

It is sometimes necessary to delay entry into any treatment program if a patient is not ready to make lifestyle changes. Every form of treatment currently available requires some degree of lifestyle accommodation, and patients who are uninterested in doing so should be advised to reconsider their goals at a later date. A reasonable strategy is to remind the patient of the health benefits of improved activity and eating habits at each visit and to reconsider efforts once a willingness to make changes is apparent.

Treatment approaches may differ for individuals who are overweight and for different classes of obesity. Simply making a diagnosis of obesity is associated with patients taking action to lose weight.[10]

Lifestyle treatment is appropriate for individuals who are overweight or obese, and pharmacotherapy can be an adjunct treatment for any class of obesity, even if medical complications are not present, and may be considered in patients who have a BMI above 27 plus a weight-related comorbid condition. Patients with class II obesity (BMI of 35.0 to 39.9) may be considered for bariatric surgery if medical treatments have failed and if serious, weight-related comorbid conditions are present. Class III obesity (BMI > 40) is one feature that might prompt consideration of a patient for bariatric surgery when medical treatments have failed.

Obesity is a chronic disease, so its treatment (Fig. 201-1) must be considered a long-term issue. Although severe dietary calorie restriction can result in substantial weight loss, body fat is invariably regained without approaches to ensure behavioral changes. Patients must learn how to make permanent changes in eating and activity behaviors to achieve permanent weight loss. Behavior modification approaches,[11] which can help patients recognize and circumvent environmental cues for sedentary behavior and overeating, can increase the likelihood that patients will accomplish these lifestyle changes,[A1] and intensive lifestyle intervention is associated with fewer hospitalizations, fewer medications, and lower health care costs in overweight or obese adults with type 2 diabetes.

Reducing energy intake is the most efficient and effective means to lose weight. For example, creating a 500 kcal/day deficit by reduced food intake will initially theoretically result in the loss of 1 pound of fat per week. It is more

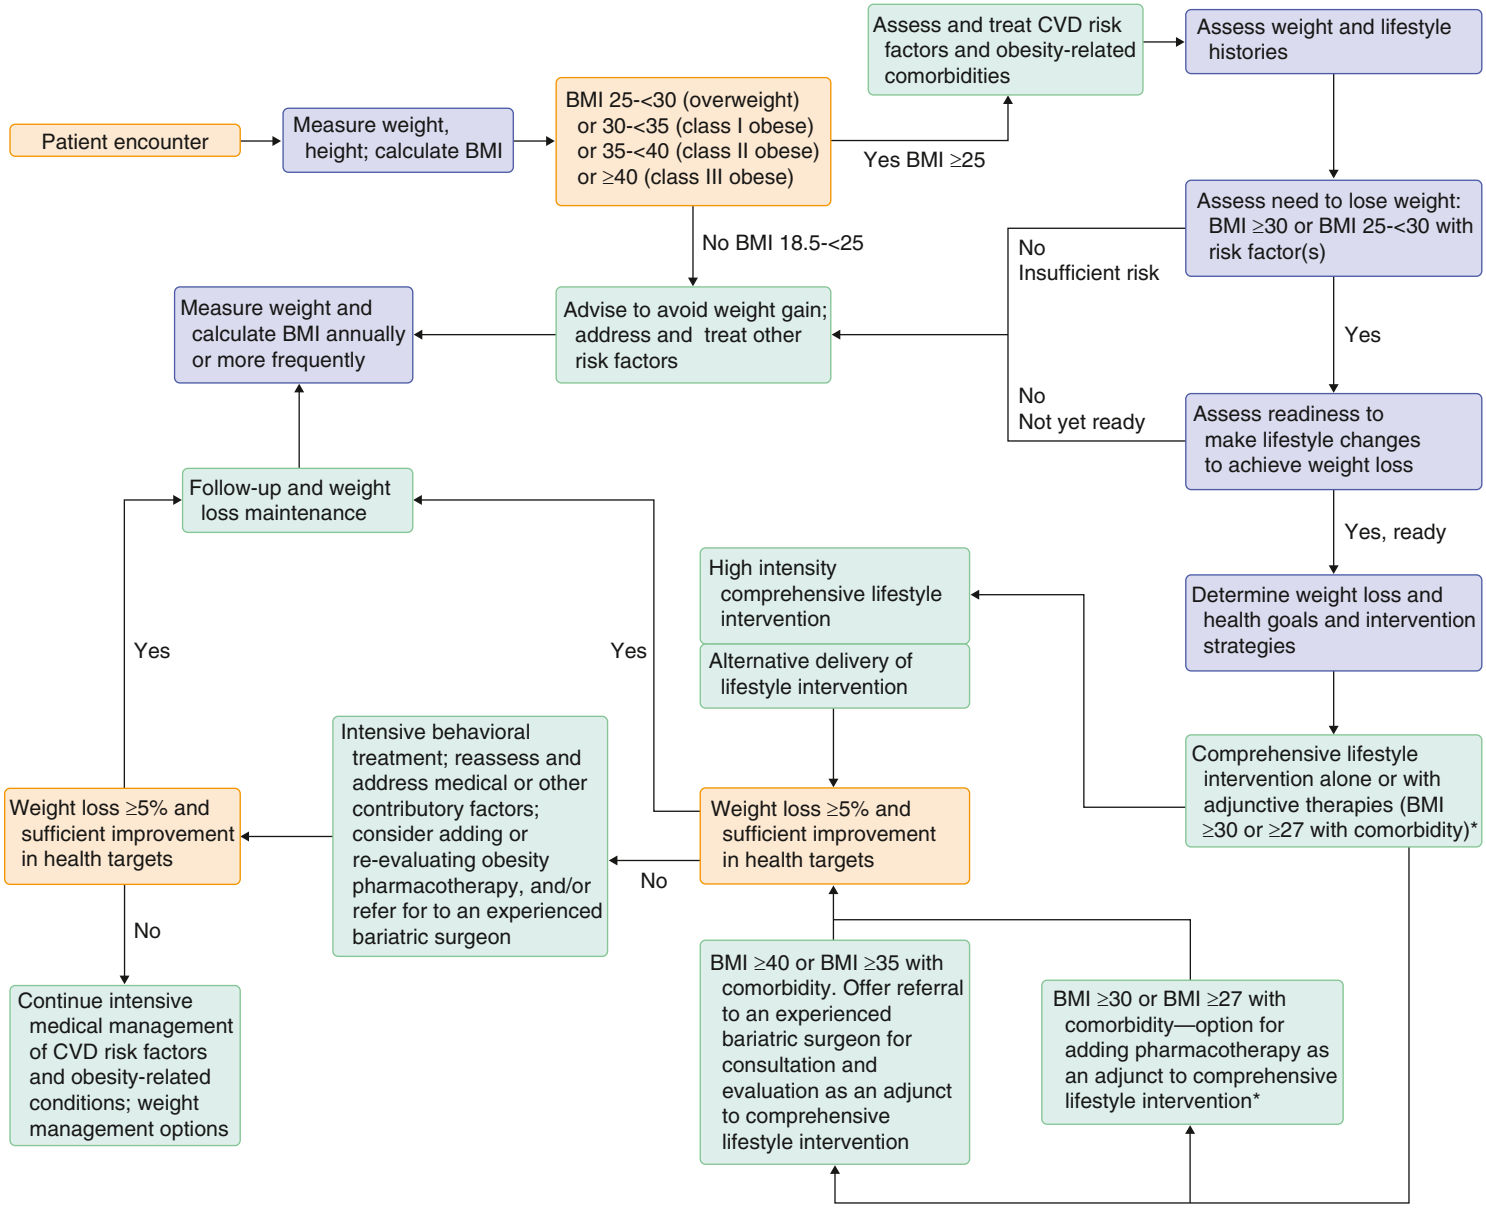


FIGURE 201-1. Flow diagram for the evaluation and management of overweight and obesity. BMI = body mass index; CVD = cardiovascular disease. *BMI cutpoint determined by the U.S. Food and Drug Administration (FDA) and listed on the package inserts of FDA-approved obesity medications. (Modified from Jensen MD, Ryan DH, Apovian CM, et al. 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society. *J Am Coll Cardiol*. 2014;63:2985-3023.)

difficult to increase energy expenditure by 500 kcal/day through exercise. Greater amounts of physical activity can prevent weight gain (or weight regain after weight loss). Some patients are able to change eating and activity habits on their own, given the proper information, whereas others require formal or informal behavior modification interventions (see later) to help make these changes. In some instances, pharmacotherapy, endoscopic obesity treatments, or bariatric surgery may be needed to treat obesity.

Diet

Changes in eating habits must be permanent if weight loss is to be maintained. An experienced registered dietitian can be helpful to evaluate a patient's eating habits and to provide the needed education. The diet history may identify eating behaviors that result in excess energy intake. Although it is important to address specific adverse eating behaviors, patients must also understand general dietary principles. Reducing the energy density of food (most commonly accomplished by reducing dietary fat) can allow patients to feel satiated while consuming fewer calories. A consensus recommendation is to prescribe a 1200 to 1500 kcal/day diet for women and a 1500 to 1800 kcal/day diet for men. Alternatively, diets that produce an energy deficit of 500 to 750 kcal/day can be recommended. Because no single diet appears to be clearly superior (e.g., low-carbohydrate compared with low-fat) over another with regard to weight loss,[A2] clinicians should prescribe any evidence-based diet that restricts selected types of food (e.g., high-carbohydrate foods, low-fiber foods, or high-fat foods) to create an energy deficit by reducing food intake. To address dyslipidemia, diabetes, and hypertension, a Mediterranean-type diet is preferred (see Fig. 13-1).[A3] Patients should be informed that consuming foods high in water and fiber (fruits, vegetables, legumes, and soups) can provide satiety without excess calories. Patients also should be counseled to reduce the intake of beverages containing substantial calories, most often sugar-sweetened beverages. Finally, a regular pattern of eating should be encouraged.

New diets are continually being promoted with the promise of easy weight loss. A common feature of these diets is the claim that special properties of certain foods help people lose weight or are the cause of obesity. If followed, most of these diets result in weight loss because of a reduced energy intake. The reduced intake can often be explained by the monotony of the diet, and no diets have been documented to cause persons to lose weight out of accordance with physiologic principles. Although a number of dietary approaches can be successful in promoting weight loss, any diet without peer-reviewed evidence for safety and success should be reviewed by a dietitian for nutritional safety.

Contrary to expectations, however, the opportunity to choose what diet to follow does not necessarily improve weight loss. More than 95% of patients embarking on self-diets or fad diets fail to maintain a significant weight loss for a time that would have meaningful health benefits.

Very low calorie diets (<800 calories per day) can achieve accelerated weight loss under expert supervision. Because the long-term results of these diets are no better and sometimes worse than the results from the standard low-calorie diet combined with behavior modification, these diets are not commonly used. Intermittent or alternate-day fasting and time-restricted eating are no better than standard weight-loss diets[A4,A5] and are not advocated as primary strategies because of inadequate evidence.

Commercial weight-loss programs (Weight Watchers, Jenny Craig, Nutrisystem) generally result in 2 to 4% more weight loss than usual education and counseling. The average weight loss is 4.8 to 6.6 kg at 6 months when conventional foods are consumed and 6.6 to 10.1 kg at 12 months when prepared food is provided. Comprehensive weight management programs delivered at academic medical centers that employ behavior modification, dietary instruction, and physical activity can achieve equally or more impressive results.

Measurement of BMR is sometimes helpful for evaluating patients who insist that they are unable to lose weight despite following a diet that contains less than 1000 kcal/day. Almost without fail, BMR measured with a reliable instrument is substantially greater than the reported food intake, thereby confirming that patients must be eating as much as, if not more, than their energy expenditure. This finding underscores the fact that most adults are unreliable in assessing their own food intake.

Physical Activity

A long-term increase in physical activity, either through the activities of daily living or through regular exercise, is key to sustained, long-term weight loss.[A6] Although exercise (fitness- and sports-related activities) is a component of thermogenesis, most adults do not exercise at high levels or for a sufficient duration to expend a large amount of energy, so focusing solely on "exercise" as the main component of physical activity will miss significant opportunities for improving energy balance. In addition, only about 100 kcal are expended by a 70-kg adult walking 1 mile. Losing weight solely by increasing exercise is impractical for most patients. However, increasing physical activity as a means of maintaining weight loss is an attainable goal for most patients.

Successful maintenance of weight loss usually entails maintaining a daily energy expenditure approximately 80 to 90% above BMR, a considerable increase for most patients. For example, someone with a BMR of 1500 kcal/day would need to expend about 1000 kcal/day in physical activity to meet this target. Activities other than exercise are important means to achieve this goal. Options for increasing physical activity include exercise (sports or fitness pursuits) and use of lifestyle approaches, such as habitually increasing the amount of walking throughout the day.

Persuading obese patients to become more active is not easy. Physicians can begin by asking patients about their current and past activity habits as well as what barriers they see to increasing physical activity. If patients agree to begin an exercise or physical activity program, they will need to set realistic goals for the amount of exercise they are going to achieve and to monitor their activity. Unlike highly fit individuals, obese sedentary adults often become so uncomfortable that they cannot continue exercising at what might be considered moderate levels of activity because their lactate threshold (the level of work that causes blood lactate concentrations to increase dramatically) is low. Even walking as slow as 3 miles per hour may exceed the lactate threshold for adults who are obese with type 2 diabetes. The ready availability of step counters and electronic activity monitoring devices built into many "smartphones" offers a practical means for patients to track physical activity throughout the day and to assess the effects of changes in lifestyle on their activity level. Many Americans take as few as 4000 to 5000 steps per day, whereas it may take as many as 15,000 to 17,000 steps per day for patients who have lost significant amounts of weight to maintain that lower weight. Gradually increasing the number of steps regularly taken during the day through a series of changes in habits (e.g., parking farther away, walking during work breaks) is more likely to result in long-term success for most persons than setting aside 2 hours or more for continuous walking. Gradual increases in physical activity also will improve fitness and eventually allow for sufficient energy expenditure to help maintain weight loss.

Behavior Modification

Patients who are unable to make changes in eating activity habits on their own or with informal office counseling may benefit from referral to an interventionist or commercial program that provides weight-loss–specific behavioral therapy.[12] The goals are to help patients modify their eating, activity, and thinking habits that predispose to obesity and focus on specific pathways to achieve the goals. As part of this process, patients are taught the benefits of and how to self-monitor (food intake, activity, environmental cues); set goals (realistic short-, medium-, and long-term goals that are specific, measurable, attainable, relevant, and time-limited); identify and leverage personal strengths to change behavior; create a healthy external environment (stimulus control—identify and modify the environmental stimuli that thwart changes in eating/activity habits); manage stress if it causes extra eating or reduces planned activity; manage emotional triggers that may cause someone to eat so as to feel better); be more mindful about eating and enjoy food more, so as to limit the amount eaten while still feeling satisfied; leverage social/community support to begin and maintain behavior change; maintain perspective; and reduce all-or-nothing thinking as a way to maintain motivation and prevent relapse.

The best weight loss results are provided by in-person, high-intensity (≥14 sessions in 6 months) comprehensive behavioral interventions, which average an 8-kg (5 to 10% of body weight) loss in 6 months, even in underserved populations.[A7] Approaches that provide electronically delivered counseling (telephone or Internet),[A8,A9] including some commercial programs, can also achieve weight loss, but generally less than with in-person approaches. Commercial programs that have published their results in peer-reviewed journals are preferred. Physicians who refer patients to programs that offer intensive, comprehensive lifestyle interventions are encouraged to obtain outcomes data from those programs.

Pharmacotherapy

Drugs to help patients lose weight[13] should be used in concert with a comprehensive lifestyle intervention by knowledgeable clinicians (Table 201-4). Antiobesity medications may be considered in patients who have not reached a weight loss goal with lifestyle treatment alone or who have a BMI greater than 30

TABLE 201-4 INDICATIONS FOR PHARMACOLOGIC TREATMENT OF OBESITY

Body mass index > 27 kg/m^2
One or more complications or conditions that are likely to improve with weight loss
Previous failure of conservative treatment with behavioral intervention, diet, and exercise
Agree to 2- to 4-wk trial of making initial changes in diet and exercise before starting pharmacotherapy
Agree to continue treatment with comprehensive lifestyle attempts while receiving support with pharmacologic treatment
Agree to periodic follow-up
Premenopausal women (able to have children) must use some form of contraception
Consider a pregnancy test on initiation of treatment if there is any possibility of pregnancy
No contraindications to the specific drug used for pharmacologic treatment

in the absence of a weight-related comorbidity or a BMI of 27-30 in the presence of a weight-related comorbidity. Weight loss achieved with medications varies substantially, with some people losing almost nothing and others occasionally losing more than 15% of their starting weight. A weight loss of 5% within 3 to 6 months of initiating therapy is considered a clinically significant response. If a person loses less than this amount, the medication should be stopped. If a person loses weight with an antiobesity medication, the benefit will likely be sustained only while they take the medication, so long-term continuous or intermittent use is required to maintain long-term benefits.

The available medications vary in cost, effectiveness, side effect profile, and associated benefits. Health insurance plans often do not cover these medications. None of these medications have been shown to be safe in pregnancy, and so women of reproductive age must be on an effective form of contraception. Knowledge of these factors for each medication will allow the provider to tailor therapy to the individual patient.

Currently Available Medications

The medications currently available for long-term use either reduce appetite or cause fat malabsorption by inhibiting pancreatic lipase. All are better than placebo for achieving weight loss.[A10]

Orlistat

Orlistat (120 mg three times daily with meals by prescription or 60 mg three times daily over the counter) causes about 30% of dietary fat to be malabsorbed, results in weight loss of about 3 to 5%, and is the safest option of the available antiobesity medications. Adverse gastrointestinal side effects, such as oily spotting, abdominal pain, excess flatus, fecal urgency, and fatty or oily stools may occur but generally decrease over time; the concomitant use of bulk-forming laxatives (e.g., psyllium, methylcellulose) can reduce these symptoms. A daily multivitamin is recommended in patients who receive long-term orlistat therapy.

Phentermine

Phentermine is the most commonly prescribed antiobesity medication (doses ranging from 8 mg to 37.5 mg per day), but it is approved as monotherapy only for short-term (3 months) use. Phentermine may increase cardiovascular morbidity by increasing pulse and blood pressure in some patients, so it should not be prescribed in patients who have uncontrolled hypertension or known coronary artery disease, or who are at high risk for cardiac ischemia.

The combination of phentermine and topiramate (7.5 mg phentermine/46 mg extended-release topiramate, or 15 mg /92 mg) can be used chronically, with the higher dose resulting in an average of an 8% weight loss at 2 years, with slightly more than half of patients achieving a 10% weight loss and 15% of patients achieving a 20% weight loss. The most common side effects are constipation, paresthesia, sinusitis, and dry mouth; the incidence of individual adverse effects diminishes significantly after the first year.

Glucagon-Like Peptide 1 Antagonists

Glucagon-like peptide-1 agonists, which are effective for diabetes (Chapter 210), are also effective for the treatment of obesity.[14] Liraglutide (3 mg per day subcutaneously) can reduce weight by an average of about 6% more than lifestyle alone, but semaglutide (2.4 mg per week subcutaneously) is more effective than liraglutide[A11] and can reduce weight by 10 to 12% more than diet and exercise alone.[A12–A14] Tirzepatide, which is a dual glucose-dependent insulinotropic polypeptide and glucagon like peptide-1 receptor agonist, can lead to substantial weight loss averaging 5.5 kg at a 5 mg subcutaneous weekly dose and nearly 9 kg at a dose of 15 mg weekly.[A15,A16] Side effects are generally similar to semaglutide.[A17] Cagrilintide, an amylin analog, is an investigational once-weekly subcutaneous drug that appears to be quite effective.[A18]

Other Options

The combination of bupropion and naltrexone results in an average weight loss of 4 to 5% more than lifestyle alone, with relatively few side effects and no abuse potential. The cardiovascular risk of this combination remains uncertain.[A19] Gelesis100 is a nonsystemic, superabsorbent hydrogel whose particles expand in the stomach after ingestion to create a sense of fullness. One capsule twice daily before meals produces about a 2% weight loss.

Choosing Among Alternatives

Each of these approved medications has advantages, side effects, and cost considerations. Physicians should consider their patients' comorbid conditions and preferences to tailor treatment for each individual. For example, semaglutide is the most effective currently available agent, but is injectable and expensive. Phentermine/topiramate is the least expensive option and the most effective oral medication, but it can have cognitive side effects and is subject to limited prescribing periods in some states. Orlistat is the lowest risk, but it has gastrointestinal side effects. Liraglutide and bupropion/naltrexone are intermediate in side effects, efficacy, and cost.

Endoscopic Treatment of Obesity

Endoscopic approaches to treating obesity include space-occupying devices in the stomach (intragastric balloons),[15] gastroesophageal stents that exert pressure on the gastric cardia to create a sensation of fullness, and gastric remodeling techniques that reduce the gastric reservoir by creating a tubular sleeve along the greater curvature of the stomach and aspiration therapy. Intragastric balloons can result in significantly more weight loss than lifestyle modifications alone[A20] and are a reasonable option in patients with a BMI over 30. Endoscopic small bowel interventions, such as excluding the proximal small intestine using impermeable polymer duodenojejunal bypass liners and ablative duodenal resurfacing techniques that regenerate the proximal small intestinal mucosal barrier in hopes of modifying ingestive behavior, are under investigation. Another approach is to insert self-assembling magnets that create a dual-path enteral bypass between the proximal jejunum or duodenum and the ileum, with the goal of diverting bile to the terminal ileum. Data currently are insufficient to guide when, if ever, these endoscopic options should be recommended.

Bariatric Surgery

Bariatric surgery, which almost always results in more weight loss than lifestyle or antiobesity medications, can be considered in patients who have a BMI of 35 to 40 plus serious weight-related comorbid conditions, especially uncontrolled type 2 diabetes, assuming prior attempts at medical treatments have failed,[16,A21] or a BMI higher than 40. The benefits of bariatric surgery compared with medical treatment include long-term reduced risks of obesity-related comorbidity; improvement or remission of type 2 diabetes, hypertension, and dyslipidemia; and a likely reduction in long-term mortality,[A22–A24] including obesity-associated cancer and cancer-related mortality.[17] However, these benefits must be balanced against a small (<0.5%) risk of death, potential surgical complications, and longer-term risks for nutritional deficiencies, new-onset depression, treatment with opioids, and the need for additional surgical procedures.

Laparoscopic approaches are routinely used for bariatric surgery because they reduce the length of hospitalization and the risk of incisional hernias compared with open procedures. Contraindications to surgery include active substance abuse, defined noncompliance or inability to comply with medical care, and schizophrenia, borderline personality disorder, or uncontrolled depression.

A multidisciplinary team (including a physician, dietitian, psychologist or psychiatrist, and experienced surgeon) is important for optimal outcome. Most successful patients will achieve weight losses of 25 to 35% of body weight but are not likely reach their ideal body weight. Follow-up to support the necessary changes in long-term behavior is recommended to optimize weight loss outcomes.

Among the available bariatric surgical techniques, procedures that only modify the capacity of the stomach (laparoscopic gastric banding) are much less effective than Roux-en-Y gastric bypass in terms of long-term weight loss. Procedures that both reduce stomach size and modify other stomach properties (e.g., sleeve gastrectomy) appear to be almost as effective as Roux-en-Y gastric bypass in terms of long-term weight loss and outright surgical success, with durable benefits in terms of type 2 diabetes, hypertension, and dyslipidemia.[A25,A26] The partial pancreaticobiliary bypass, the very long limb Roux-en-Y gastric bypass, and the duodenal switch procedures create malabsorption that results in greater weight loss than with the standard Roux-en-Y gastric bypass. Unfortunately, the incidence of severe and even fatal vitamin and mineral deficiencies (Chapter 199) is much higher with these procedures.

Surgical mortality and morbidity (e.g., infection, anastomotic leak, wound dehiscence) are low in centers with expertise, despite the high-risk population. Laparoscopic gastric banding is rarely used now because of the inferior long-term weight loss results and late complications of band slippage, erosion, and weight regain.

After surgery, approximately 70% of patients achieve success, with almost all of the weight loss occurring during the first 1 to 2 years. Long-term (>5 year) success rates are outstanding in good programs. Up to two thirds of patients regain 20% or more of their maximum weight loss in the years following the weight nadir, so postoperative weight regain remains an important clinical challenge. Despite this regain, weight remains substantially below preoperative levels for most patients.

Careful long-term follow-up is needed to ensure adequate protein, calorie, vitamin, and mineral nutrition. Supplemental vitamin B_{12}, iron, and calcium are routinely added to standard multivitamins. The most common nutritional consequences of malabsorptive procedures are disorders of calcium and vitamin D metabolism, although many severely obese patients have low vitamin D levels even before surgery (Chapter 226). An increase in the bone alkaline phosphatase level may signal deficiency of calcium or vitamin D. Low plasma vitamin D levels and low urinary calcium excretion should prompt aggressive replacement therapy. Iron deficiency, other fat-soluble vitamin deficiencies, and copper deficiency can occur more than 5 to 10 years after surgery.

Pancreatogenous hypoglycemia can develop after bariatric surgical procedures; symptoms are primarily postprandial and can be quite severe. Medical management by specialists in this field is the best approach for these patients.

PREVENTION

The dramatic increase in the prevalence of obesity during the past few decades strongly suggests that preventive strategies are needed. Public health approaches that emphasize education have been almost uniformly unsuccessful at preventing weight gain or producing weight loss. Public health strategies that virtually impose behavior change are more successful in this regard. Unless widespread efforts are made to address the problem of obesity, it is likely that its prevalence and complications will become an ever-increasing health burden.

PROGNOSIS

On a population basis, life expectancy declines as BMI rises within the obese range. The loss of life is about 3 years for a BMI of 30 to 39, 7 years for a BMI of 40 to 44, 9 years for a BMI of 45 to 49, 10 years for a BMI of 50 to 54, and 14 years for a BMI of 55 to 59. Data are insufficient to estimate life expectancy of patients who lose weight. In markedly obese patients, however, bariatric surgery is associated with about a 6-year increase in life expectancy compared with current medical management,[18] but life expectancy still remains less than in the general population.[19]

202 APPROACH TO THE PATIENT WITH ENDOCRINE DISEASE

DAVID R. CLEMMONS AND LYNNETTE K. NIEMAN

Most endocrine disorders are due to either an excess or a deficiency of a hormone that is transported in the systemic circulation and therefore result in multiorgan manifestations. Since individual hormones commonly have multiple sites of action, patients rarely present with a single set of symptoms or signs isolated to only one organ system. Generalized nonspecific symptoms such as weakness, difficulty concentrating, lack of energy, and change in appetite are common. Any single symptom evaluated in isolation is rarely helpful, and a constellation of findings is typically required to point to the correct diagnosis (Table 202-1).

To diagnose an endocrinologic condition, a careful longitudinal history is critical. The duration of hormone excess or deficiency often dictates the severity of symptoms, and the characterization of progressive symptoms over time can be very helpful in selecting diagnostic tests, substantiating the need for treatment, and choosing the optimal treatment. The physical examination helps to confirm the likelihood of a diagnosis; for example, the presence of a symmetrically enlarged thyroid gland indicates that Graves disease is the most likely cause of hyperthyroidism (Chapter 207). Even if endocrine disorders are diagnosed by biochemical screening in the absence of symptoms or signs of overt disease (e.g., hyperparathyroidism; Chapter 227), a thorough history and physical examination are still important to determine whether the patient is truly in the asymptomatic phase of the disease and whether observation or therapy is the preferred option. A careful temporal history of a symptomatic change may also assist with the differential diagnosis—for example, whether a thyroid mass is due to a hemorrhagic cyst (i.e., occurring suddenly) or is an adenoma that evolved over an extended period. A thorough general history and physical examination may identify diseases associated with endocrinologic abnormalities, such as cancers that secrete ectopic hormones.

An accurate family history can indicate a need for genetic testing[1] or familial screening. A thorough evaluation of medication use is also mandatory. Some medications can mask the symptoms of overt endocrine disease, such as β-blockers in hyperthyroidism, and others can exacerbate the findings, such as use of a thiazide diuretic in hyperparathyroidism. Medications also may confound laboratory evaluation, such as diuretics in patients with hyperaldosteronism or acetaminophen in patients screened for pheochromocytoma; in such situations medications may need to be discontinued before testing. Finally, it may be difficult to obtain an accurate history of certain complaints. For example, in evaluating male sexual dysfunction (Chapter 216), a corroborating history from his partner may be needed.

The off-target effects of treatments provide another example of the importance of a complete medical history. A variety of medical treatments also may cause either hormone excess or deficiency. For example, administration of high-dose glucocorticoid therapy for immune suppression can result in Cushing syndrome,[2] and abrupt discontinuation of such therapy can cause acute adrenal insufficiency because of suppression of the pituitary-adrenal axis (Chapter 208). Immunotherapy with checkpoint inhibitors (Chapter 164) may cause both endocrine excess and deficiency, most commonly involving the thyroid gland. Many traditional chemotherapies adversely affect reproductive endocrine function, and radiation therapy (Chapter 18) of tumors may cause endocrine deficiencies.

TABLE 202-1 SYMPTOM CONSTELLATIONS SUGGESTING SPECIFIC ENDOCRINE DISORDERS

SYMPTOM CONSTELLATION	DIAGNOSIS
Weakness, fatigue, anorexia, loss of appetite, postural hypotension	Adrenal insufficiency
Cold intolerance, dry skin, constipation, weight gain	Hypothyroidism
Fatigue, easy bruising, striae, proximal muscle weakness, weight gain, hypertension, acne	Cushing syndrome
Weight loss, increased appetite, palpitations, tremor, emotional lability, diffuse hair thinning	Hyperthyroidism
Galactorrhea, amenorrhea, headaches	Prolactinoma
Weight loss, anorexia, loss of pubic and axillary hair	Hypopituitarism
Episodic palpitations, tremor, anxiety, headaches, sweating, weight loss	Pheochromocytoma
Episodic flushing, palpitations, abdominal cramping, and diarrhea	Carcinoid syndrome

COMMON SYMPTOMS OF ENDOCRINOLOGIC DISEASE

Signs and symptoms common to many endocrine disorders and the general population without endocrine disorders include weakness and fatigue, abnormal menstrual function, constipation or diarrhea (Chapters 122 and 126), generalized hair loss or male pattern balding (Chapter 409), recurrent or episodic headaches (Chapter 367), altered libido (Chapters 216 and 219), polyuria and nocturia, weight gain or loss[3] (Chapters 164 and 201), depression (Chapter 362), altered mood, acne (Chapter 406), dry skin, and vitiligo (Chapter 408). By contrast, pain is not common except in an acute endocrine emergency such as diabetic ketoacidosis or adrenal crisis, although chronic bone pain is seen in hyperparathyroidism (Chapter 227) and osteomalacia (Chapter 226).

PHYSICAL EXAMINATION

The physical examination can confirm or refute findings ascertained by a medical history (Table 202-2). Thyroid disease is often first suspected based on the physical examination. Endocrinopathies lead to skin changes that may occur early in the illness and progress over time and may assist in identifying the diagnosis. For example, striae (Chapter 208), plethora, easy bruisability, acanthosis nigricans, and hyperpigmentation may suggest Cushing syndrome.

Edema may be an early sign of hormone-producing tumors that result in salt retention, including Cushing syndrome and hyperaldosteronism (Chapter 208). Measurement of upper trunk to leg-length ratios and arm span is helpful in establishing the timing and onset of puberty in primary gonadal disorders.

On pelvic examination, palpation may identify polycystic ovaries (Chapter 217) or suggest the absence of ovarian tissue. The absence of a uterus is important in the differential diagnosis of pseudohermaphroditism, and the evaluation of external genitalia can be important in establishing the presence of congenital adrenal hyperplasia. Vaginal dryness and breast atrophy are signs of severe estrogen deficiency.

Mental status changes (Chapter 361) occur frequently with extreme hypercalcemia, Cushing syndrome, and hyperthyroidism. Many primary endocrine disorders are associated with characteristic psychiatric manifestations (Chapter 362).

TABLE 202-2 PHYSICAL SIGNS THAT SUGGEST SPECIFIC ENDOCRINE DISORDERS

Hyperpigmentation of palms, extensor surfaces, and buccal mucosa	Adrenal insufficiency
Facial plethora, moon facies, striae, purpura, proximal muscle weakness	Cushing syndrome
Skin tags, acral enlargement, prognathism, orthodontia, cardiomegaly, increased size of hand/foot/tongue	Acromegaly
Proptosis, lid lag, symmetrically diffuse thyroid enlargement, abnormal extraocular movements	Graves disease
Hyperreflexia, moist skin, thin hair, tachycardia, wide pulse pressure, flow murmur, bruit over thyroid, tremor	Hyperthyroidism
Hyperkeratosis, myxedema, hyporeflexia, coarse hair	Hypothyroidism
Retinal microaneurysms, macular edema, motor nerve defect, inability to detect monofilament or vibratory sensation	Diabetic retinopathy/ neuropathy
Short stature, web neck, loss of tears, coarctation of the aorta	Turner syndrome
Shield-like chest, short fourth metacarpal	Primary ovarian failure
Bowing of the legs	Hypophosphatemic rickets
Orthostatic blood pressure	Pheochromocytoma
Galactorrhea	Hyperprolactinemia
Purple-hued flushing	Midgut carcinoid

ABSTRACT

Endocrine disorders can be classified as states in which there is too much or too little of one or more hormones. Since many hormones have multiple sites of action, a deficiency or excess of a hormone can cause many possible symptoms and signs, not all of which may be present, particularly in early stages of the disease. Thus, a very complete history and physical examination are often required to determine whether these entities are the cause of the patient's complaints. Laboratory evaluation is usually needed to validate the clinical clues, except when the disorders are severe and clinically unmistakable. The treatment of endocrine excess disorders is generally directed to resection of the causative (overactive) tissue, whereas the treatment of endocrine deficiency is generally directed to replacement of the missing hormones with a satisfactory exogenous substitute.

LABORATORY EVALUATION

Asymptomatic endocrine diseases are frequently diagnosed because of abnormalities on radiologic or hormonal tests. The most common radiologic conundrums occur in patients who are noted incidentally to have small pituitary, thyroid, or adrenal masses. Evaluation for a functionally active tumor is usually necessary, even though only a minority will test positive. For pituitary tumors (Chapter 205), testing includes measurement of a baseline serum prolactin level and, in cases with suggestive symptoms, of 24-hour urine cortisol and growth hormone after glucose suppression. In patients with incidentally found adrenal masses ("incidentalomas"; Chapter 208),[4,5] the tumor heterogeneity, size (>4 cm) and density (>10 Hounsfield units), hypertension or hypokalemia, and symptoms and signs of Cushing syndrome should be evaluated. If any of these are present, the patient must be evaluated for Cushing syndrome, adrenal cortical carcinoma, hyperaldosteronism, and pheochromocytoma[6] (Chapters 208 and 209).

Measurements of the active hormone in blood, urine, or saliva are generally sufficient.[7] Occasionally, measurement of a metabolite (such as 25-hydroxycholecalciferol, a vitamin D metabolite) is more reliable (Chapter 224). Measurement of hormones with a very long plasma half-life (e.g., thyroxine) can be obtained at any time of day. However, other hormones (e.g., growth hormone) are secreted episodically, so a static measurement may or may not be indicative of hormone excess or deficiency. In these cases, suppression or stimulation testing is used to confirm the diagnosis. Usually, an exogenous substance (e.g., adrenocorticotropic hormone [ACTH]) is administered either orally or intravenously, and the production of the hormone (e.g., cortisol) by the gland is either stimulated or suppressed. Hormones are measured using structural (e.g., tandem mass spectometry) or antibody-based (e.g., immunoassay) techniques, which may yield very different results depending on the specificity of the antibody. Careful interpretation should take these differences into account.[8]

Many hormones (e.g., cortisol, T4, T3, estradiol, testosterone) are bound to proteins as they circulate in the blood. Medications or concomitant illnesses can result in a major change in the concentration of the binding protein, which in turn alters the concentration of the total hormone. This problem can be obviated either by measuring the binding protein itself or by direct measurement of the free hormone, such as measurement of free thyroxine (Chapter 207).[9]

Static hormone measurements are often used for screening—for example, morning cortisol for hypoadrenalism. Stimulation or suppression testing is then used to confirm the diagnosis. In some cases, plasma measurements are much less reliable than urinary testing (e.g., a single morning cortisol level to identify Cushing syndrome; Chapter 208). In these situations, 24-hour urinary measurement of hormone is often required to document overproduction. Urinary assays have the advantage of providing integrative assessment over 24 hours and thus are less likely to be susceptible to measurement errors owing to episodic hormonal secretion. Occasionally, measurements of other substances, such as electrolytes or metabolites, are also informative for confirming the diagnosis. For example, measurement of 24-hour urinary calcium can be important in the differential diagnosis of hypercalcemia (Chapter 227). Metabolites in the urine may be extremely important in the evaluation of adrenal disorders and in documentation of pheochromocytoma (Chapter 209)[10] and carcinoid syndrome (Chapter 213).[11] Simultaneous measurement of two substances is extremely helpful in the diagnosis of some disorders. For example, measurement of simultaneous serum calcium and parathyroid hormone (PTH) is important for confirming the presence of hyperparathyroidism (Chapter 227). Likewise, simultaneous measurement of blood glucose and insulin are needed to screen for an insulin-producing tumor (Chapter 211). Indirect measurement of hormonal status can also be important; for example, insulin-like growth factor (IGF)-I, which is inducible by growth hormone, reflects total daily secretion of growth hormone (Chapter 205), and hemoglobin A_{1c} is an integrative measurement of long-term blood sugar control in diabetes (Chapter 210).

Imaging studies are commonly used in endocrine diagnosis. Magnetic resonance imaging and computed tomography are helpful in evaluating pituitary (Chapters 205 and 206) and adrenal masses (Chapter 208). The ability of the thyroid gland to take up radioactive iodine is used to evaluate its functional status and the etiology of nodules (Chapter 207). Bone mineral density testing[12] is used to document osteoporosis and to evaluate established fracture syndromes (Chapter 225). Imaging also can be combined with hormonal measurements. For example, venous sampling can confirm the presence of an aldosteronoma (Chapter 208) and the location of PTH-secreting tumors (Chapter 237). Similarly, intraoperative measurements of hormones with a short half-life, such as intraoperative PTH (Chapter 227), can help determine whether surgical removal of the hormone-secreting tumor has been adequate. The primary use of biopsy in endocrinologic diagnosis is ultrasound-guided, fine-needle aspiration of the thyroid gland (Chapter 207) to determine whether further diagnostic evaluation or therapeutic intervention is necessary.

GENETIC EVALUATION

Genetic testing in endocrinologic diagnosis is commonplace. Polymerase chain reaction amplification of DNA obtained from peripheral blood cells is often used to determine the presence of a specific disorder. Genetic testing is extremely useful in differential diagnosis, for determining prognosis, and for deciding whether family screening is required (e.g., in the presence of pheochromocytoma or paraganlioma).[13]

EVALUATION OF THE RESPONSE OF AN ENDOCRINE DISEASE TO TREATMENT

Localized causes of hormone excess syndromes are typically treated surgically by removal of the particular endocrine gland or tumor that is oversecreting the hormone. Appropriate follow-up is needed to confirm that the disease has truly been cured by the resection, whether residual disease is present, and, if so, whether a repeat operation is likely to result in remission. These decisions generally are made in consultation with surgeons and radiotherapists. When hormone excess syndromes do not respond adequately to surgery, the cause is often multisited, and medical treatment is required to control symptoms.

For endocrine deficiencies, hormone replacement therapy is usually successful and can be documented by a resolution of symptoms and signs, hormone levels, and indirect tests (e.g., potassium, blood urea nitrogen, and creatinine levels in the case of adrenal insufficiency). Sometimes the efficacy of substitution therapy can be best assessed by laboratory testing, such as measurement of thyroid-stimulating hormone during thyroxine replacement (Chapter 207). Proper replacement therapy requires knowledge of pharmacology of the particular synthetic hormone. For example, synthetic glucocorticoids vary greatly in their half-life, so the dosage and timing of administration are important for patients receiving these hormones. Some patients, such as patients with hypopituitarism (Chapter 205), require substitution with multiple hormones, whose interactions must be coordinated.

203 PRINCIPLES OF ENDOCRINOLOGY

ALLEN M. SPIEGEL

The principal manifestation of most endocrine diseases is over- or undersecretion of one or more hormones, but the causes of endocrine disease are not unique to endocrinology as a subspecialty of medicine. Major causes of endocrine disease that are shared with diseases of other organ systems include benign or malignant proliferation of endocrine cells; destruction of endocrine cells by autoimmune, infectious, or other infiltrative processes; mutations in genes expressed by endocrine cells; and alterations in endocrine cell function caused by metabolic abnormalities or drugs. The understanding of hormone action and endocrine diseases has been improved not only by classic physiology and biochemistry but also by newer technologies such as whole-exome sequencing,[1] metabolomics,[2] and bioinformatics.[3]

Endocrine action, by which a hormone secreted into the blood stream acts at a distance, can be contrasted with paracrine action, which is when a growth factor or other signaling molecule secreted from one cell acts on adjacent cells, and autocrine action, when a cell secretes a signaling molecule that acts on the same cell. However, the distinction among endocrine, paracrine, and autocrine actions is not sharp. In some cases, a factor such as parathyroid hormone–related peptide (PTHrP) that acts physiologically in paracrine fashion during normal bone development may act as an endocrine factor in the syndrome of humoral hypercalcemia of malignancy (Chapter 227).

LABORATORY EVALUATION

Asymptomatic endocrine diseases are frequently diagnosed because of abnormalities on radiologic or hormonal tests. The most common radiologic conundrums occur in patients who are noted incidentally to have small pituitary, thyroid, or adrenal masses. Evaluation for a functionally active tumor is usually necessary, even though only a minority will test positive. For pituitary tumors (Chapter 205), testing includes measurement of a baseline serum prolactin level and, in cases with suggestive symptoms, of 24-hour urine cortisol and growth hormone after glucose suppression. In patients with incidentally found adrenal masses ("incidentalomas"; Chapter 208),[4,5] the tumor heterogeneity, size (>4 cm) and density (>10 Hounsfield units), hypertension or hypokalemia, and symptoms and signs of Cushing syndrome should be evaluated. If any of these are present, the patient must be evaluated for Cushing syndrome, adrenal cortical carcinoma, hyperaldosteronism, and pheochromocytoma[6] (Chapters 208 and 209).

Measurements of the active hormone in blood, urine, or saliva are generally sufficient.[7] Occasionally, measurement of a metabolite (such as 25-hydroxycholecalciferol, a vitamin D metabolite) is more reliable (Chapter 224). Measurement of hormones with a very long plasma half-life (e.g., thyroxine) can be obtained at any time of day. However, other hormones (e.g., growth hormone) are secreted episodically, so a static measurement may or may not be indicative of hormone excess or deficiency. In these cases, suppression or stimulation testing is used to confirm the diagnosis. Usually, an exogenous substance (e.g., adrenocorticotropic hormone [ACTH]) is administered either orally or intravenously, and the production of the hormone (e.g., cortisol) by the gland is either stimulated or suppressed. Hormones are measured using structural (e.g., tandem mass spectometry) or antibody-based (e.g., immunoassay) techniques, which may yield very different results depending on the specificity of the antibody. Careful interpretation should take these differences into account.[8]

Many hormones (e.g., cortisol, T4, T3, estradiol, testosterone) are bound to proteins as they circulate in the blood. Medications or concomitant illnesses can result in a major change in the concentration of the binding protein, which in turn alters the concentration of the total hormone. This problem can be obviated either by measuring the binding protein itself or by direct measurement of the free hormone, such as measurement of free thyroxine (Chapter 207).[9]

Static hormone measurements are often used for screening—for example, morning cortisol for hypoadrenalism. Stimulation or suppression testing is then used to confirm the diagnosis. In some cases, plasma measurements are much less reliable than urinary testing (e.g., a single morning cortisol level to identify Cushing syndrome; Chapter 208). In these situations, 24-hour urinary measurement of hormone is often required to document overproduction. Urinary assays have the advantage of providing integrative assessment over 24 hours and thus are less likely to be susceptible to measurement errors owing to episodic hormonal secretion. Occasionally, measurements of other substances, such as electrolytes or metabolites, are also informative for confirming the diagnosis. For example, measurement of 24-hour urinary calcium can be important in the differential diagnosis of hypercalcemia (Chapter 227). Metabolites in the urine may be extremely important in the evaluation of adrenal disorders and in documentation of pheochromocytoma (Chapter 209)[10] and carcinoid syndrome (Chapter 213).[11] Simultaneous measurement of two substances is extremely helpful in the diagnosis of some disorders. For example, measurement of simultaneous serum calcium and parathyroid hormone (PTH) is important for confirming the presence of hyperparathyroidism (Chapter 227). Likewise, simultaneous measurement of blood glucose and insulin are needed to screen for an insulin-producing tumor (Chapter 211). Indirect measurement of hormonal status can also be important; for example, insulin-like growth factor (IGF)-I, which is inducible by growth hormone, reflects total daily secretion of growth hormone (Chapter 205), and hemoglobin A_{1c} is an integrative measurement of long-term blood sugar control in diabetes (Chapter 210).

Imaging studies are commonly used in endocrine diagnosis. Magnetic resonance imaging and computed tomography are helpful in evaluating pituitary (Chapters 205 and 206) and adrenal masses (Chapter 208). The ability of the thyroid gland to take up radioactive iodine is used to evaluate its functional status and the etiology of nodules (Chapter 207). Bone mineral density testing[12] is used to document osteoporosis and to evaluate established fracture syndromes (Chapter 225). Imaging also can be combined with hormonal measurements. For example, venous sampling can confirm the presence of an aldosteronoma (Chapter 208) and the location of PTH-secreting tumors (Chapter 237). Similarly, intraoperative measurements of hormones with a short half-life, such as intraoperative PTH (Chapter 227), can help determine whether surgical removal of the hormone-secreting tumor has been adequate. The primary use of biopsy in endocrinologic diagnosis is ultrasound-guided, fine-needle aspiration of the thyroid gland (Chapter 207) to determine whether further diagnostic evaluation or therapeutic intervention is necessary.

GENETIC EVALUATION

Genetic testing in endocrinologic diagnosis is commonplace. Polymerase chain reaction amplification of DNA obtained from peripheral blood cells is often used to determine the presence of a specific disorder. Genetic testing is extremely useful in differential diagnosis, for determining prognosis, and for deciding whether family screening is required (e.g., in the presence of pheochromocytoma or paraganlioma).[13]

EVALUATION OF THE RESPONSE OF AN ENDOCRINE DISEASE TO TREATMENT

Localized causes of hormone excess syndromes are typically treated surgically by removal of the particular endocrine gland or tumor that is oversecreting the hormone. Appropriate follow-up is needed to confirm that the disease has truly been cured by the resection, whether residual disease is present, and, if so, whether a repeat operation is likely to result in remission. These decisions generally are made in consultation with surgeons and radiotherapists. When hormone excess syndromes do not respond adequately to surgery, the cause is often multisited, and medical treatment is required to control symptoms.

For endocrine deficiencies, hormone replacement therapy is usually successful and can be documented by a resolution of symptoms and signs, hormone levels, and indirect tests (e.g., potassium, blood urea nitrogen, and creatinine levels in the case of adrenal insufficiency). Sometimes the efficacy of substitution therapy can be best assessed by laboratory testing, such as measurement of thyroid-stimulating hormone during thyroxine replacement (Chapter 207). Proper replacement therapy requires knowledge of pharmacology of the particular synthetic hormone. For example, synthetic glucocorticoids vary greatly in their half-life, so the dosage and timing of administration are important for patients receiving these hormones. Some patients, such as patients with hypopituitarism (Chapter 205), require substitution with multiple hormones, whose interactions must be coordinated.

203 PRINCIPLES OF ENDOCRINOLOGY

ALLEN M. SPIEGEL

The principal manifestation of most endocrine diseases is over- or undersecretion of one or more hormones, but the causes of endocrine disease are not unique to endocrinology as a subspecialty of medicine. Major causes of endocrine disease that are shared with diseases of other organ systems include benign or malignant proliferation of endocrine cells; destruction of endocrine cells by autoimmune, infectious, or other infiltrative processes; mutations in genes expressed by endocrine cells; and alterations in endocrine cell function caused by metabolic abnormalities or drugs. The understanding of hormone action and endocrine diseases has been improved not only by classic physiology and biochemistry but also by newer technologies such as whole-exome sequencing,[1] metabolomics,[2] and bioinformatics.[3]

Endocrine action, by which a hormone secreted into the blood stream acts at a distance, can be contrasted with paracrine action, which is when a growth factor or other signaling molecule secreted from one cell acts on adjacent cells, and autocrine action, when a cell secretes a signaling molecule that acts on the same cell. However, the distinction among endocrine, paracrine, and autocrine actions is not sharp. In some cases, a factor such as parathyroid hormone–related peptide (PTHrP) that acts physiologically in paracrine fashion during normal bone development may act as an endocrine factor in the syndrome of humoral hypercalcemia of malignancy (Chapter 227).

ABSTRACT

The principles of endocrinology are presented: what is a hormone; regulation of hormone synthesis and secretion; hormone transport and metabolism; mechanism of hormone action; endocrine diseases caused by mutations in signaling components, by mutations leading to neoplasia, and by autoimmune destruction; new approaches to the study of endocrine disease.

tyrosine kinase receptor

REGULATION OF HORMONE SYNTHESIS AND SECRETION

Two broad categories of hormone synthesis are responsible for the synthesis of peptide hormones and steroid hormones, including the active form of vitamin D, thyroid hormones, catecholamines, and other nonpeptide hormones. In the former category, hormone structure is encoded genetically, and mRNA translation yields a protein precursor (pre-prohormone) that is generally cleaved through successive steps to yield the mature secreted product. Some protein precursors such as proopiomelanocortin contain multiple hormonal products, in this case adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (MSH), and endorphins. In certain situations, inappropriate secretion of immature hormones creates a pathologic condition (e.g., excessive proinsulin secretion by insulinomas). Post-translational modifications occur for some hormones, such as disulfide bond formation for vasopressin and insulin; C-peptide cleavage for insulin; and glycosylation of the pituitary glycoprotein hormones, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Mutations in genes that encode peptide hormones can lead to disruption of normal hormone synthesis or secretion, a rare cause of hormone deficiency. Peptide hormones are typically stored in secretory granules, and they are secreted by an exocytosis process that is regulated by calcium (Ca^{2+}) and other factors. For steroids and other nonpeptide hormones, hormone synthesis is accomplished by a series of enzymatic steps that act on precursors (cholesterol for steroid hormones; aromatic amino acids for thyroid hormones, catecholamines, and related compounds). Mutations in genes encoding enzymes responsible for one or more steps in hormone synthesis can lead to hormone deficiency and/or excess of another hormone, as in congenital adrenal hyperplasia (Chapter 214).

Negative feedback regulation is the general principle that governs normal hormone synthesis and secretion. For endocrine glands whose growth and hormone secretion are stimulated by pituitary trophic hormones (gonads, adrenal cortex, thyroid), the hormone secreted by the gland acts directly on cognate pituitary trophic cells (e.g., cortisol acting on ACTH-secreting pituitary corticotrophs) to suppress hormone secretion (Fig. 203-1). Conversely, a physiologically meaningful reduction in target gland hormone secretion leads to increased pituitary trophic hormone secretion. In many other cases, negative feedback regulation operates without the pituitary as an intermediate (e.g., PTH secretion from the parathyroid glands regulates extracellular Ca^{2+} homeostasis, and Ca^{2+} feeds back directly on parathyroid cells via a Ca^{2+} sensing receptor to regulate PTH secretion). Chronic hormone deficiency with resultant loss of negative feedback can lead to hypersecretion of the cognate trophic hormone and even to neoplastic proliferation of trophic hormone–secreting cells. Examples include Nelson syndrome (Chapter 205) in which corticotroph tumors form after adrenalectomy,[4] and tertiary hyperparathyroidism in which parathyroid adenomas occur in the setting of chronic hypocalcemia (Chapter 227). In some adrenal cortical disorders, hormone deficiency leads to loss of negative feedback of trophic hormone secretion, which in turn causes pathologic hypersecretion of alternative steroid hormones. The various forms of congenital adrenal hyperplasia (Chapter 214)[5] are caused by mutations in one of the several enzymes in the cortisol biosynthetic pathway. The most common such mutation, which is 21-hydroxylase deficiency, can lead to virilization in female infants, with excessive adrenal androgen secretion caused by ACTH stimulation in the face of inability to synthesize cortisol. Inhibition of enzymatic steps in hormone synthesis, such as aromatase inhibitors to decrease estrogen formation in estrogen receptor–positive forms of breast cancer (Chapter 183), may be an important therapeutic target.

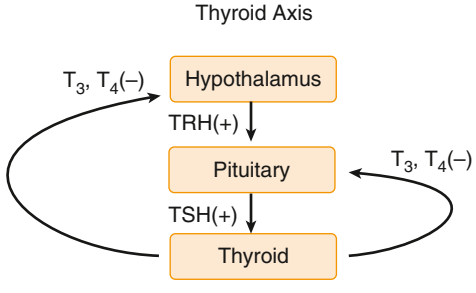

FIGURE 203-1. Hypothalamic-pituitary-thyroid axis illustrating negative feedback regulation. Following thyroid-stimulating hormone (TSH) secretion by the pituitary, the thyroid gland secretes triiodothyronine (T_3) and thyroxine (T_4), which feed back on the hypothalamus and pituitary to suppress further increases in thyrotropin-releasing hormone (TRH) and TSH secretion.

Hormone hypersecretion syndromes, in which excessive hormone secretion occurs in the face of "normal" levels of the factor that ordinarily suppresses the cognate hormone, are by definition caused by some intrinsic defect in negative feedback suppression. This defect may be caused by neoplastic proliferation of hormone-secreting cells, so that "basal" hormone secretion from the increased mass of cells exceeds physiologic levels. This defect also may be due to alterations in the intrinsic "set-point" for negative feedback suppression of hormone secretion. In practice, it may be impossible to differentiate between these two mechanisms, and they are not mutually exclusive.

Hormone secretion is subject to many additional forms of regulation beyond simple negative feedback suppression. These regulatory mechanisms include metabolic, neural, and other internal and environmental inputs. The temporal pattern of hormone secretion is often related to diurnal rhythms, as classically seen for cortisol, and also pulsatility. Changes in gonadotropin secretion during the menstrual cycle (Chapter 218) and during the course of puberty (Chapter 214) are striking examples of complex regulation of temporal patterns of hormone secretion.

HORMONE TRANSPORT AND METABOLISM

Most peptide hormones circulate as the free peptide, but insulin-like growth factor-I (IGF-I) uniquely binds to a number of specialized binding proteins. Steroid and thyroid hormones are lipophilic molecules that circulate largely in protein-bound form. Specialized binding proteins for cortisol, androgens, estrogens, and thyroid hormones are selective for their cognate hormone. The free circulating hormone concentration is only a small fraction of the total hormone measured by routine analytic methods. Binding protein abnormalities can occur in liver disease because most are synthesized by the liver. Thus, the determination of free as opposed to total plasma hormone concentration may be critical to accurate diagnosis in certain clinical conditions.

Hormone metabolism is another critical determinant of action for some hormones. For testosterone (Chapter 216), thyroxine (Chapter 207), and vitamin D (Chapter 199), enzymatic conversion to more potent hormones—dihydrotestosterone formation in target tissues such as skin by 5-α reductase, thyroxine conversion to triiodothyronine by deiodinases, and 1,25 dihydroxyvitamin D formation by sequential hydroxylations in the liver and kidney—are all critical to normal hormone action. Defects in these metabolic steps leads to impaired hormone action. Even some peptide hormones such as angiotensin must undergo enzymatic conversion from secreted precursor form to generate the active hormone.

MECHANISM OF HORMONE ACTION

A hormone circulating in the blood stream in minute concentrations must be recognized by its specific target cells so it can regulate physiologic processes within them. Receptors, which are proteins in these target cells, bind their cognate hormones with high affinity and specificity. Two broad classes of receptors are cell surface receptors that typically span the plasma membrane one or more times (Fig. 203-2) and nuclear receptors that either reside in the nucleus or reside initially in the cytoplasm but then subsequently translocate into the nucleus (Fig. 203-3).

Hormones regulate cellular physiologic processes such as secretion of hormones, enzymes, and other compounds; muscle contraction; growth; and proliferation. Signal transduction is the general term for the biochemical steps between when the hormone binds to the receptor and the resulting alterations in cellular physiology. Most peptide and protein hormones (e.g., insulin, growth hormone, ACTH) bind to cell surface receptors that can be classified according to the mechanism of signal transduction to which they are coupled (e.g., G protein–coupled,[6] receptor tyrosine,[7] or serine kinase, JAK/STAT coupled; see Fig. 203-2). Cell surface receptors may generate "second messengers," which in turn regulate a kinase cascade. The activation of the receptor may result in rapid effects, such as exocytosis of secretory granules, but longer-term actions involving gene regulation may also be a consequence of the activation of second messengers and the resulting kinase cascade. Steroid and thyroid hormones and vitamin D bind to members of the nuclear receptor family; the latter act as "ligand-regulated" transcription factors to regulate gene expression (see Fig. 203-3).[8]

MECHANISMS OF ENDOCRINE DISEASE

Endocrine disease may be caused by acquired or inherited errors in signal transduction. "Specificity spillover" is a clinically important phenomenon in which supraphysiologic concentrations of a hormone lead to binding to and activation of a noncognate receptor for a related hormone. Examples include: hypoglycemia with nonislet cell tumors that secrete IGF-II, which binds to the insulin receptor; skin hyperpigmentation in patients with

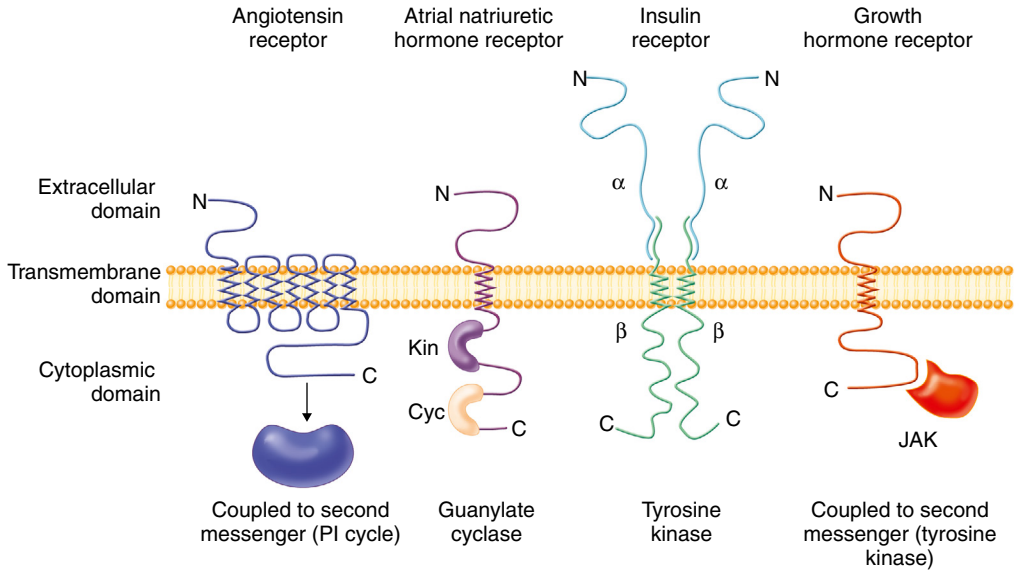

FIGURE 203-2. Structures of different types of peptide hormone receptors. PI = phosphoinositide.

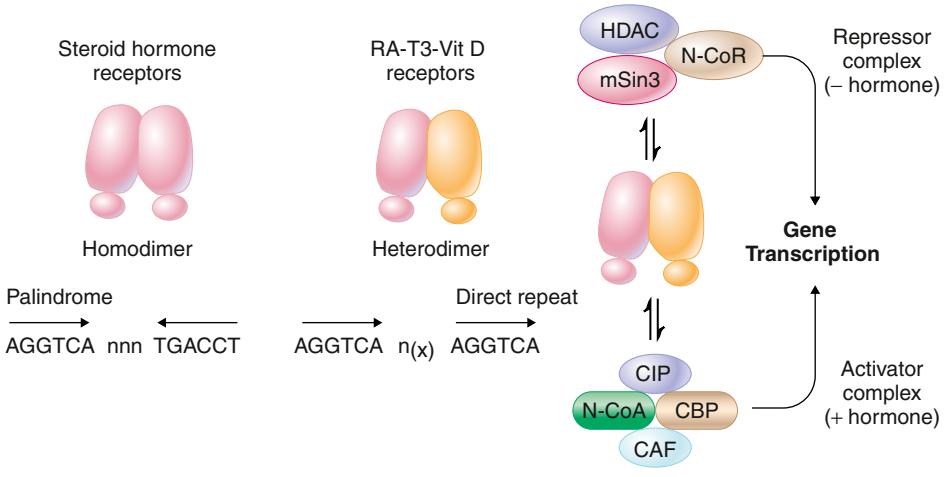

FIGURE 203-3. How steroid hormone receptors function. *Left*, Glucocorticoid receptor family members bind as homodimers to palindromic DNA sites. Thyroid hormone receptor family members bind primarily as heterodimers with retinoid X receptor to direct repeat DNA sites separated by varying numbers of base pairs. *Right*, As a result of hormone binding, repressor complexes dissociate and activator complexes bind to nuclear receptors. Repressor complexes contain histone deacetylase (HDAC), and activator complexes contain histone acetylase (CAF). CBP = CREB binding protein (CREB = cAMP response element binding protein); CIP = cyclin-dependent kinase interacting protein; mSin3 = mammalian homologue of the yeast *SIN3* gene; N-CoA = nuclear receptor coactivator protein; N-CoR = nuclear receptor corepressor protein; RA-T3-Vit D = retinoic acid–triiodothyronine-vitamin D.

Addison disease (Chapter 208), in whom excessive ACTH secretion activates the melanocortin receptor in melanocytes that are normally regulated by MSH; and hyperthyroidism (Chapter 207) in pregnant women whose high human chorionic gonadotropin (HCG) concentrations activate the TSH receptor.

Mutations in one component of a signal transduction pathway can lead either to hormone "resistance" or hormone-independent activation. In the former, patients present with an apparent hormone deficiency, but direct hormone measurement reveals high concentrations of bioactive hormone that fails to act owing to target organ resistance. In the latter, patients present with apparent endocrine hyperfunction, but direct measurement reveals suppressed hormone concentration owing to intact negative feedback. Receptor-inactivating mutations that lead to hormone-resistance diseases[9] have been identified for both the cell surface and nuclear classes of receptors (Table 203-1). Mutations that constitutively activate G protein–coupled receptors have been identified in many endocrine diseases (Table 203-2).

Benign and malignant forms of endocrine neoplasia are caused by somatic and germline mutations in genes that regulate cell proliferation (Chapter 213). Autoimmune destruction of endocrine glands and the resulting deficiencies in hormone secretion may be caused by inherited mutations in immune regulatory genes (Chapter 212) or can be acquired, particularly owing to treatment of cancer with immune checkpoint inhibitors.[10,11]

TABLE 203-1 ENDOCRINE DISEASES CAUSED BY HORMONE RECEPTOR LOSS-OF-FUNCTION MUTATIONS

RECEPTOR	DISEASE	INHERITANCE
V2 vasopressin	Nephrogenic diabetes insipidus	X-linked
ACTH	Familial ACTH resistance	Autosomal recessive
Melanocortin 4	Early onset obesity	Autosomal recessive
Leptin	Early onset obesity	Autosomal recessive
Growth hormone	Laron dwarfism	Autosomal recessive
Insulin	Severe insulin resistance	Autosomal recessive or dominant
Glucocorticoid	Glucocorticoid resistance	Autosomal dominant or recessive
Thyroid hormone	Thyroid hormone resistance	Autosomal dominant or recessive
Vitamin D	Rickets and alopecia syndrome	Autosomal recessive

ACTH = adrenocorticotropic hormone.

TABLE 203-2 ENDOCRINE DISEASES CAUSED BY RECEPTOR GAIN-OF-FUNCTION MUTATIONS

RECEPTOR	DISEASE	INHERITANCE
LH	Familial male precocious puberty	Autosomal dominant
TSH	Sporadic hyperfunctional thyroid nodules	Noninherited (somatic)
Ca^{2+} sensing	Familial hypocalcemic hypercalciuria	Autosomal dominant

Ca^{2+} = calcium; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

NEUROENDOCRINOLOGY AND THE NEUROENDOCRINE SYSTEM

ROY E. WEISS

NEUROENDOCRINE REGULATION

Neuroendocrinology is the interactions between the nervous system and the endocrine system's metabolic and hormonal homeostatic activities. One role the nervous system has is to connect the environment with the body. The most important environmental factors are temperature and light, which fluctuate in a predictable way each day. Humans have a circadian clock (Chapter 374) to assure that physiology and behavior are attuned to the time of day.[1] The nervous system senses temperature and light, and it uses them as clues to guide eating, activity, sleep, and other essential life functions. The microbiome (Chapter 257) may also influence complex feeding behaviors via the neuroendocrine axis. The neurohypophysial neurons originate from the paraventricular and supraoptic nuclei and traverse the hypothalamic-pituitary stalk to the posterior pituitary, where nerve endings release vasopressin and oxytocin. Hypophysiotropic neurons are localized to specific hypothalamic nuclei, from which they project their axons to the median eminence, where they secrete hormones, which in turn stimulate or inhibit the release of peptides and bioamines into the proximal hypothalamic-pituitary vessels (Fig. 204-1). The blood supply of the median eminence comes from the superior hypophysial artery and its richly arborized capillary beds that extend into the median eminence and then coalesce to form the portal veins that traverse the pituitary stalk and terminate in the pituitary gland. The neuroendocrine system relies on a series of feedback loops, which regulate pituitary hormones as well as the levels of target organ hormones. The target organ hormones regulate both the hypothalamus and the pituitary gland to complete the feedback loop. Perturbations in feedback loops can be altered by factors such as circadian rhythms (circadian periodicity), physiologic and psychological stress, nutritional status, and response to systemic illness.

Hypophysiotropic Hormones

The hypophysiotropic hormones regulate the secretion of pituitary hormones. Some feedback loops are redundant, and some hypophysiotropic hormones exert effects on more than one pituitary hormone. Furthermore, the hypophysiotrophic hormones themselves are regulated by signals higher in the brain, such as the thalamus and the molecular clocks.

Thyrotropin-Releasing Hormone

The primary neuroendocrine function of thyrotropin-releasing hormone (TRH) is to stimulate the synthesis and release of both thyroid-stimulating hormone (TSH) and prolactin. TRH is synthesized from the precursor prepro-TRH and then processed to biologically active TRH. Tanycytes that line the third ventricle contain an enzyme, pyroglutamyl peptidase II, that degrades TRH to regulate the amount of TRH that is transported to the pars distalis of the anterior pituitary gland. In hypothyroidism (Chapter 207), the increased TRH synthesis and binding to the thyrocyte TRH receptors result in increased levels of TSH and prolactin. Correction of hypothyroidism with thyroid hormone replacement decreases the elevated levels of both TSH and prolactin. Conversely, in primary hyperthyroidism, TSH levels are markedly suppressed owing to a direct effect of thyroid hormone on mRNA expression of TRH in the paraventricular nucleus (Fig. 204-2). TRH is the major regulator of the synthesis and secretion of TSH, but the role of TRH for regulating prolactin-releasing factor is less well understood.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH) is a 10–amino acid peptide. The neurons that produce GnRH originate outside the central nervous system in the epithelium of the medial part of the olfactory placode. This location is relevant to Kallmann syndrome (Chapter 214),[2] in which GnRH deficiency is associated with congenital agenesis of the olfactory bulbs. One of its genetic forms is caused by a loss of anosmin, which is a protein that facilitates the embryologic migration of these GnRH-producing neurons.

The primary function of GnRH is to control the reproductive axis. GnRH, which is released in a pulsatile manner into the hypothalamohypophyseal portal circulation, subsequently reaches the anterior pituitary gland, where it stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Once the GnRH neuron migrates to the hypothalamus, a GnRH pulse generator is activated. In early postnatal life, GnRH secretion increases, thereby leading to temporary activation of gonadal hormone production, referred to as "minipuberty." During childhood, the gonads respond to exogenous LH and FSH stimulation but remain quiescent because the endogenous pulsatile GnRH release is suppressed until puberty.

GnRH results in the differential secretion of LH and FSH owing to variable sensitivity of the feedback loop for steroid and peptide hormones, as well as variable sensitivity to GnRH. The pulsatile secretion of GnRH directly increases its own receptor, whereas continuous administration of GnRH is associated with a decrease. In women, positive and negative regulation of steroid hormone feedback in the hypothalamic-pituitary-gonadal axis occurs at both the hypothalamic and pituitary levels. The hypothalamic effects depend on the amplitude and frequency of the pulsed release of GnRH, whereas the pituitary effects are modulated by the gonadotropin response to GnRH. In males, testosterone decreases pulsatile GnRH secretion, with a resulting

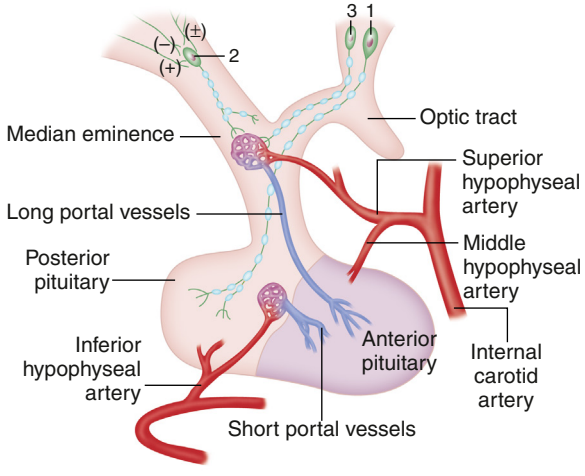

FIGURE 204-1. Neuroendocrine organization of the hypothalamus and pituitary gland. The posterior pituitary is fed by the inferior hypophyseal artery and the hypothalamus by the superior hypophyseal artery, both branches of the internal carotid artery. Most of the blood supply to the anterior pituitary is venous by way of the long portal vessels, which connect the portal capillary beds in the median eminence to the venous sinusoids in the anterior pituitary. Hypophysiotropic neuron 3 in the parvocellular division of the paraventricular nucleus and neuron 2 in the arcuate nucleus are shown to terminate in the median eminence on portal capillaries. These neurons of the tuberoinfundibular system secrete hypothalamic-releasing and -inhibiting hormones into the portal veins for conveyance to the anterior pituitary gland. Neuron 2 is innervated by monoaminergic neurons. Note that the multiple inputs to such neurons, using neuron 2 as an example, can be stimulatory, inhibitory, or neuromodulatory, in which another neuron may affect neurotransmitter release. Neuron 1 represents a peptidergic neuron originating in the magnocellular division of the paraventricular nucleus or supraoptic nucleus and projecting directly to the posterior pituitary by way of the hypothalamic-neurohypophyseal tract. NEUROENDOCRINOLOGY AND THE NEUROENDOCRINE SYSTEM

ROY E. WEISS

NEUROENDOCRINE REGULATION

Neuroendocrinology is the interactions between the nervous system and the endocrine system's metabolic and hormonal homeostatic activities. One role the nervous system has is to connect the environment with the body. The most important environmental factors are temperature and light, which fluctuate in a predictable way each day. Humans have a circadian clock (Chapter 374) to assure that physiology and behavior are attuned to the time of day.[1] The nervous system senses temperature and light, and it uses them as clues to guide eating, activity, sleep, and other essential life functions. The microbiome (Chapter 257) may also influence complex feeding behaviors via the neuroendocrine axis. The neurohypophysial neurons originate from the paraventricular and supraoptic nuclei and traverse the hypothalamic-pituitary stalk to the posterior pituitary, where nerve endings release vasopressin and oxytocin. Hypophysiotropic neurons are localized to specific hypothalamic nuclei, from which they project their axons to the median eminence, where they secrete hormones, which in turn stimulate or inhibit the release of peptides and bioamines into the proximal hypothalamic-pituitary vessels (Fig. 204-1). The blood supply of the median eminence comes from the superior hypophysial artery and its richly arborized capillary beds that extend into the median eminence and then coalesce to form the portal veins that traverse the pituitary stalk and terminate in the pituitary gland. The neuroendocrine system relies on a series of feedback loops, which regulate pituitary hormones as well as the levels of target organ hormones. The target organ hormones regulate both the hypothalamus and the pituitary gland to complete the feedback loop. Perturbations in feedback loops can be altered by factors such as circadian rhythms (circadian periodicity), physiologic and psychological stress, nutritional status, and response to systemic illness.

Hypophysiotropic Hormones

The hypophysiotropic hormones regulate the secretion of pituitary hormones. Some feedback loops are redundant, and some hypophysiotropic hormones exert effects on more than one pituitary hormone. Furthermore, the hypophysiotrophic hormones themselves are regulated by signals higher in the brain, such as the thalamus and the molecular clocks.

Thyrotropin-Releasing Hormone

The primary neuroendocrine function of thyrotropin-releasing hormone (TRH) is to stimulate the synthesis and release of both thyroid-stimulating hormone (TSH) and prolactin. TRH is synthesized from the precursor prepro-TRH and then processed to biologically active TRH. Tanycytes that line the third ventricle contain an enzyme, pyroglutamyl peptidase II, that degrades TRH to regulate the amount of TRH that is transported to the pars distalis of the anterior pituitary gland. In hypothyroidism (Chapter 207), the increased TRH synthesis and binding to the thyrocyte TRH receptors result in increased levels of TSH and prolactin. Correction of hypothyroidism with thyroid hormone replacement decreases the elevated levels of both TSH and prolactin. Conversely, in primary hyperthyroidism, TSH levels are markedly suppressed owing to a direct effect of thyroid hormone on mRNA expression of TRH in the paraventricular nucleus (Fig. 204-2). TRH is the major regulator of the synthesis and secretion of TSH, but the role of TRH for regulating prolactin-releasing factor is less well understood.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH) is a 10–amino acid peptide. The neurons that produce GnRH originate outside the central nervous system in the epithelium of the medial part of the olfactory placode. This location is relevant to Kallmann syndrome (Chapter 214),[2] in which GnRH deficiency is associated with congenital agenesis of the olfactory bulbs. One of its genetic forms is caused by a loss of anosmin, which is a protein that facilitates the embryologic migration of these GnRH-producing neurons.

The primary function of GnRH is to control the reproductive axis. GnRH, which is released in a pulsatile manner into the hypothalamohypophyseal portal circulation, subsequently reaches the anterior pituitary gland, where it stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Once the GnRH neuron migrates to the hypothalamus, a GnRH pulse generator is activated. In early postnatal life, GnRH secretion increases, thereby leading to temporary activation of gonadal hormone production, referred to as "minipuberty." During childhood, the gonads respond to exogenous LH and FSH stimulation but remain quiescent because the endogenous pulsatile GnRH release is suppressed until puberty.

GnRH results in the differential secretion of LH and FSH owing to variable sensitivity of the feedback loop for steroid and peptide hormones, as well as variable sensitivity to GnRH. The pulsatile secretion of GnRH directly increases its own receptor, whereas continuous administration of GnRH is associated with a decrease. In women, positive and negative regulation of steroid hormone feedback in the hypothalamic-pituitary-gonadal axis occurs at both the hypothalamic and pituitary levels. The hypothalamic effects depend on the amplitude and frequency of the pulsed release of GnRH, whereas the pituitary effects are modulated by the gonadotropin response to GnRH. In males, testosterone decreases pulsatile GnRH secretion, with a resulting

ABSTRACT

Neuroendocrinology refers to the area of endocrinology in which the nervous system interacts with the endocrine system to link neural activity with metabolic and hormonal homeostatic activity. Neuroendocrine diseases include congenital disorders, tumors, inflammatory and infiltrative diseases, trauma, and irradiation.

decrease in the amplitude and frequency of the gonadotropin pulse as well as a decreased gonadotropin response to exogenous GnRH.

In addition to pulsatility and regulation of GnRH receptors, kisspeptin may indirectly stimulate LH and FSH release by stimulating GnRH neurons. Kisspeptin levels rise just before puberty. Mutations in the kisspeptin gene have been associated with hypothalamic hypogonadism and impaired pubertal development, thereby demonstrating its role in the reproductive axis.

The negative feedback effects of inhibin, a peptide produced by testicular Sertoli cells and ovarian granulosa cells, are predominantly on FSH at the pituitary level, where inhibin causes a decrease in the sensitivity of gonadotrophs to GnRH. A related ovarian protein, activin, stimulates the basal and GnRH-stimulated synthesis and release of FSH from the pituitary, but its primary effect is to promote the response of ovarian granulosa cells to FSH. Another gonadal peptide, follistatin, inhibits the GnRH-induced rise in FSH that follows oophorectomy, primarily by binding to activin. These ovarian peptides are also found in the pituitary; therefore they may have additional local effects on gonadotropin secretion.

Pulsatile administration of exogenous GnRH is very successful for restoring normal sexual function and fertility in patients who have hypogonadotropic hypogonadism (Chapter 216) secondary to GnRH deficiency. Long-acting GnRH agonists also are useful to downregulate GnRH receptors and gonadotropin secretion in a variety of conditions, including precocious puberty (Chapter 214), prostate cancer (Chapter 186), breast cancer (Chapter 183), uterine fibroids (Chapter 184), and endometriosis (Chapter 218). Direct GnRH antagonists, which competitively bind to the GnRH receptor, are used for similar conditions.

Somatostatin

Somatostatin (also known as somatotropin release–inhibiting factor) inhibits the secretion of growth hormone. The interactions between somatostatin and growth hormone–releasing hormone (GHRH) and their effects on the secretion of growth hormone are complex. Growth hormone secretory episodes are associated with increased secretion of GHRH, often accompanied by low somatostatin levels. By comparison, basal or trough levels of growth hormone are associated with lower levels of GHRH and more elevated levels of somatostatin. Somatostatin also inhibits both the basal and stimulated TSH secretion. However, growth hormone is about 10-fold more sensitive to inhibition by somatostatin than is TSH, thereby suggesting that the physiologic role of somatostatin in inhibiting TSH secretion is limited. Other tissues with somatostatin include the gut mucosa, D cells of the pancreatic islets, and the myenteric neural plexus. By its paracrine and endocrine actions, somatostatin suppresses the secretion of insulin, glucagon, gastrin, secretin, cholecystokinin, vasoactive intestinal polypeptide (VIP), and other gastrointestinal hormones, which in turn regulate functions such as gastric acid secretion, gastric emptying, gallbladder contraction, and splanchnic blood flow. Somatostatin analogs are used to treat acromegaly (Chapter 205), carcinoid tumors (Chapter 213), VIP-secreting tumors (Chapter 213), TSH-secreting pituitary tumors (Chapter 205), and islet cell tumors (Chapter 211).[3]

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) stimulates the release of equimolar amounts of adrenocorticotropic hormone (ACTH), β-endorphin, β-lipotropin, melanocyte-stimulating hormone (MSH), and other peptides that are generated from proopiomelanocortin. CRH and vasopressin have synergistic effects on the release of ACTH. For example, the release of ACTH in response to stress is mediated 75% via CRH and 25% by vasopressin. However, since the releases of CRH and vasopressin are not always coordinated, stress can selectively activate the vasopressin-containing subset of CRH neurons. In a feedback loop, cortisol decreases ACTH secretion at both the hypothalamic and the pituitary levels. ACTH and β-endorphin also feed back negatively to decrease the release of CRH by the hypothalamus. Central bioamines, opioids, and peptides also influence the secretion of CRH. Inflammatory monokines, including interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α, stimulate the synthesis and release of CRH and vasopressin from the hypothalamus. The resulting increase in cortisol then reduces the intensity of the inflammatory response and the related release of monokines, thereby completing the feedback loop. CRH receptors, which are widely distributed in the brain, are activated by the sympathetic nervous system and suppressed by the parasympathetic nervous system. CRH may also help regulate body weight, because overfeeding increases leptin levels, which stimulate CRH, which in turn inhibits appetite and increases energy expenditure.

Biosynthetic human CRH is helpful for differentiating Cushing disease from ectopic ACTH syndrome (Chapter 208), with the finding that patients with Cushing disease respond with a greater than 35% increment, whereas those with ectopic ACTH secretion have a lesser response. If the results are equivocal, CRH testing during bilateral inferior petrosal sinus sampling for ACTH often provides additional discriminatory information.

Growth Hormone–Releasing Hormone

GHRH dose-dependently stimulates growth hormone secretion. Repetitive administration of GHRH can release enough growth hormone in children with GHRH deficiency to increase insulin-like growth factor (IGF)-I levels and accelerate growth. The negative feedback of both IGF-I and growth hormone on the secretion of growth hormone decreases GHRH and increases somatostatin. This feedback effect is clinically relevant, as evidenced by high circulating growth hormone levels in IGF-I–deficient states such as renal insufficiency (Chapter 116) and cirrhosis (Chapter 139). In children in whom mutations in the growth hormone receptor make them unresponsive to growth hormone (also known as Laron-type dwarfism), IGF-I levels are very low and levels of growth hormone are correspondingly elevated.

A separate growth hormone–stimulating system involves a distinct receptor, termed the *growth hormone secretagogue* receptor, which interacts with a 28–amino acid peptide called ghrelin, which initially was isolated from the stomach. Both growth hormone secretagogue receptor and ghrelin messenger RNA are present in the human hypothalamus and pituitary. The physiologic interaction of ghrelin with GHRH and somatostatin is complex. In addition to a direct stimulatory effect on the pituitary, ghrelin amplifies secretion of growth hormone by indirect hypothalamic actions. However, ghrelin appears to be more important for the regulation of appetite and food intake.

Prolactin Inhibitory Factor

The inhibitory component of hypothalamic regulation of prolactin secretion predominates over the stimulatory component. Dopamine is the major factor that inhibits prolactin in most physiologic circumstances (e.g., lactation), such as when a rising prolactin level is accompanied by a simultaneous fall in dopamine, as well as a rise in prolactin-releasing factors such as VIP. When endogenous dopamine receptors are blocked by drugs, such as the antipsychotic agents, prolactin levels rise. Lesions that interrupt the basal hypothalamic neuronal pathways that carry dopamine to the median eminence

or interrupt portal blood flow (e.g., craniopharyngiomas or other large mass lesions) decrease the amount of dopamine that reaches the pituitary and can cause hyperprolactinemia.

Prolactin-Releasing Factor

Hypothalamic peptides other than TRH also have prolactin-releasing factor activity. VIP stimulates the synthesis and release of prolactin in hypothalamic-pituitary portal blood. Within the VIP precursor, another similarly sized peptide (peptide histidine methionine) also has prolactin-releasing factor activity. Prolactin-releasing peptide, which is a hypothalamic factor with main effects on the brain, participates in the regulation of food intake and energy expenditure.

Endogenous Opioid Peptides

Endogenous opioid peptides, which have a common 5–amino acid sequence at their amino terminals (Tyr-Gly-Gly-Phe-Met [or Leu]), bind to endogenous opioid receptors. The opioid μ-receptor mediates most of the opioid endocrine effects and analgesia (Chapter 26). Its primary peptide ligand is β-endorphin, which is derived from proopiomelanocortin. For the opioid δ-receptor, which mediates behavioral, analgesic, and endocrine effects, the principal peptide ligands are met- and leu-enkephalins that are derived from proenkephalin A. Naloxone is not as effective for blocking the δ-receptor as for blocking the μ-receptor. The κ-receptor, which mediates sedation and ataxia, binds principally to dynorphin and the neoendorphins. A fourth receptor, which is partly homologous with the δ-receptor, binds to nociception, an endogenous 17–amino acid peptide.

Proopiomelanocortin, which is a 31-kD precursor peptide, contains ACTH, β-lipotropin, and β-endorphin. Its major cleavage products in the anterior pituitary are ACTH and β-lipotropin, and much of the latter is then processed into β-endorphin. In the intermediate lobe of the pituitary, the major products are α-melanocyte stimulating hormone (α-MSH), corticotropin-like intermediate peptide, β-endorphin, and γ-lipotropin. In the brain, however, proopiomelanocortin is processed primarily to β-endorphin, γ-lipotropin, and ACTH, with most of the ACTH then further processed to corticotropin-like intermediate peptide and α-MSH. The pentapeptide enkephalins are derived from the 28-kD precursor proenkephalin A. Neuronal perikarya containing the enkephalins are widely distributed in the brain. Dynorphin is a 17–amino acid peptide that is derived from a 28-kD precursor called proenkephalin B or prodynorphin. This peptide, as well as shorter peptides called α-neoendorphin (with 10 amino acids) and β-neoendorphin (with 9 amino acids), react almost exclusively with the κ-receptor. Nociceptin, which is a 17–amino acid peptide that is derived from a κ precursor called pronociceptin, and its receptor, which also is present in the hypothalamus as well as in other areas of the brain, are sources of monoamine neurotransmitters. Nociceptin appears to have an antiopioid or antinociceptive effect. Opioid peptides that influence hormone secretion in the anterior pituitary are produced through modulation of hypothalamic bioamines and hypophysiotropic factors.

The various opioid peptides and their receptors are linked to a number of bodily functions, including stress, mental illness, narcotic tolerance and dependence, pregnancy, eating, drinking, gastrointestinal function, learning, memory, reward, cardiovascular responses, respiration, thermoregulation, locomotor activity, seizures, brain electrical activity, and neuroimmune activity. Endogenous opioids inhibit gonadotropin secretion via their action on GnRH secretion. The exogenous administration of analogues of β-endorphin or enkephalin increase serum levels of growth hormone and prolactin, but blocking endogenous opioid pathways with naloxone does not alter basal or stimulated levels of growth hormone or prolactin. Opioids provide negative feedback on the secretion of ACTH and β-endorphin, and naloxone increases basal and stimulated levels of ACTH. Overall, the effects of the endogenous opioids on the normal physiologic regulation of the various pituitary hormones in humans is minimal. However, exogenous opioids in pharmacologic doses can impair the secretion of GnRH and gonadotropin, thereby causing hypogonadism (reduced libido, sexual function, and fertility) and adrenal insufficiency (by impairing the secretion of CRH and ACTH).

Central Nervous System Rhythms and Neuroendocrine Function

Pituitary hormones are secreted in a pulsatile fashion but in the context of underlying rhythms. A pituitary hormone's pulse amplitude reflects the amount of releasing hormone as well as factors that alter the pituitary's sensitivity to that releasing hormone. The pulse amplitude will be reduced by inhibitory factors (e.g., GHRH versus somatostatin), feedback from target organ hormones, nutritional factors, and prior stimulation that can deplete the releasable hormone pool. Pulse frequency is driven by the frequency at which the hypophysiotropic factor is released, which in turn is regulated by the hypothalamic pulse generator system.

The pituitary has an intrinsic rhythm of small amplitudes at a frequency of every 2 to 10 minutes. The pulsatile release of hypophysiotropic-releasing factors is superimposed on this intrinsic rhythm with or without the withdrawal of a corresponding inhibitory factor. Ultradian rhythms are less than 1 day, circadian rhythms have a periodicity of about 24 hours (synchronized by an environmental cue such as the light-dark cycle), and infradian rhythms have a periodicity of more than 24 hours. The suprachiasmatic nucleus functions as a circadian pacemaker and receives light-induced electrical impulses from the retina and then transmits these impulses to the pineal gland, where they are converted to hormonal signals. Infradian rhythms include the gravitational influence of the moon, which guides the menstrual cycle.

Circadian and infradian rhythms are modulated by the sleep-wake cycle. For example, the secretion of growth hormone, prolactin, ACTH, and pubertal LH are linked more to the sleep-wake cycle than to the dark-light cycle (E-Fig. 204-1). Each of these hormones increases to its maximal level after the onset of sleep. The marked diurnal variation in ACTH and cortisol is often an indication of whether this system is functioning normally. Loss of this diurnal rhythm occurs when the regulation of CRH is abnormal, which may occur with depression, excessive alcohol intake, or autonomous secretion of ACTH in Cushing disease (Chapter 208). In fact, a diagnostic test for Cushing syndrome is the presence of a disrupted diurnal cortisol rhythm.

Hypothalamic-pituitary axes are blunted with aging. Furthermore, changes in the hormonal milieu associated with sleep deprivation and disruption of the axes result in significant metabolic sequelae, such as hypertension and impaired glucose tolerance.

NEUROENDOCRINE DISEASE

DISEASES OF THE HYPOTHALAMUS

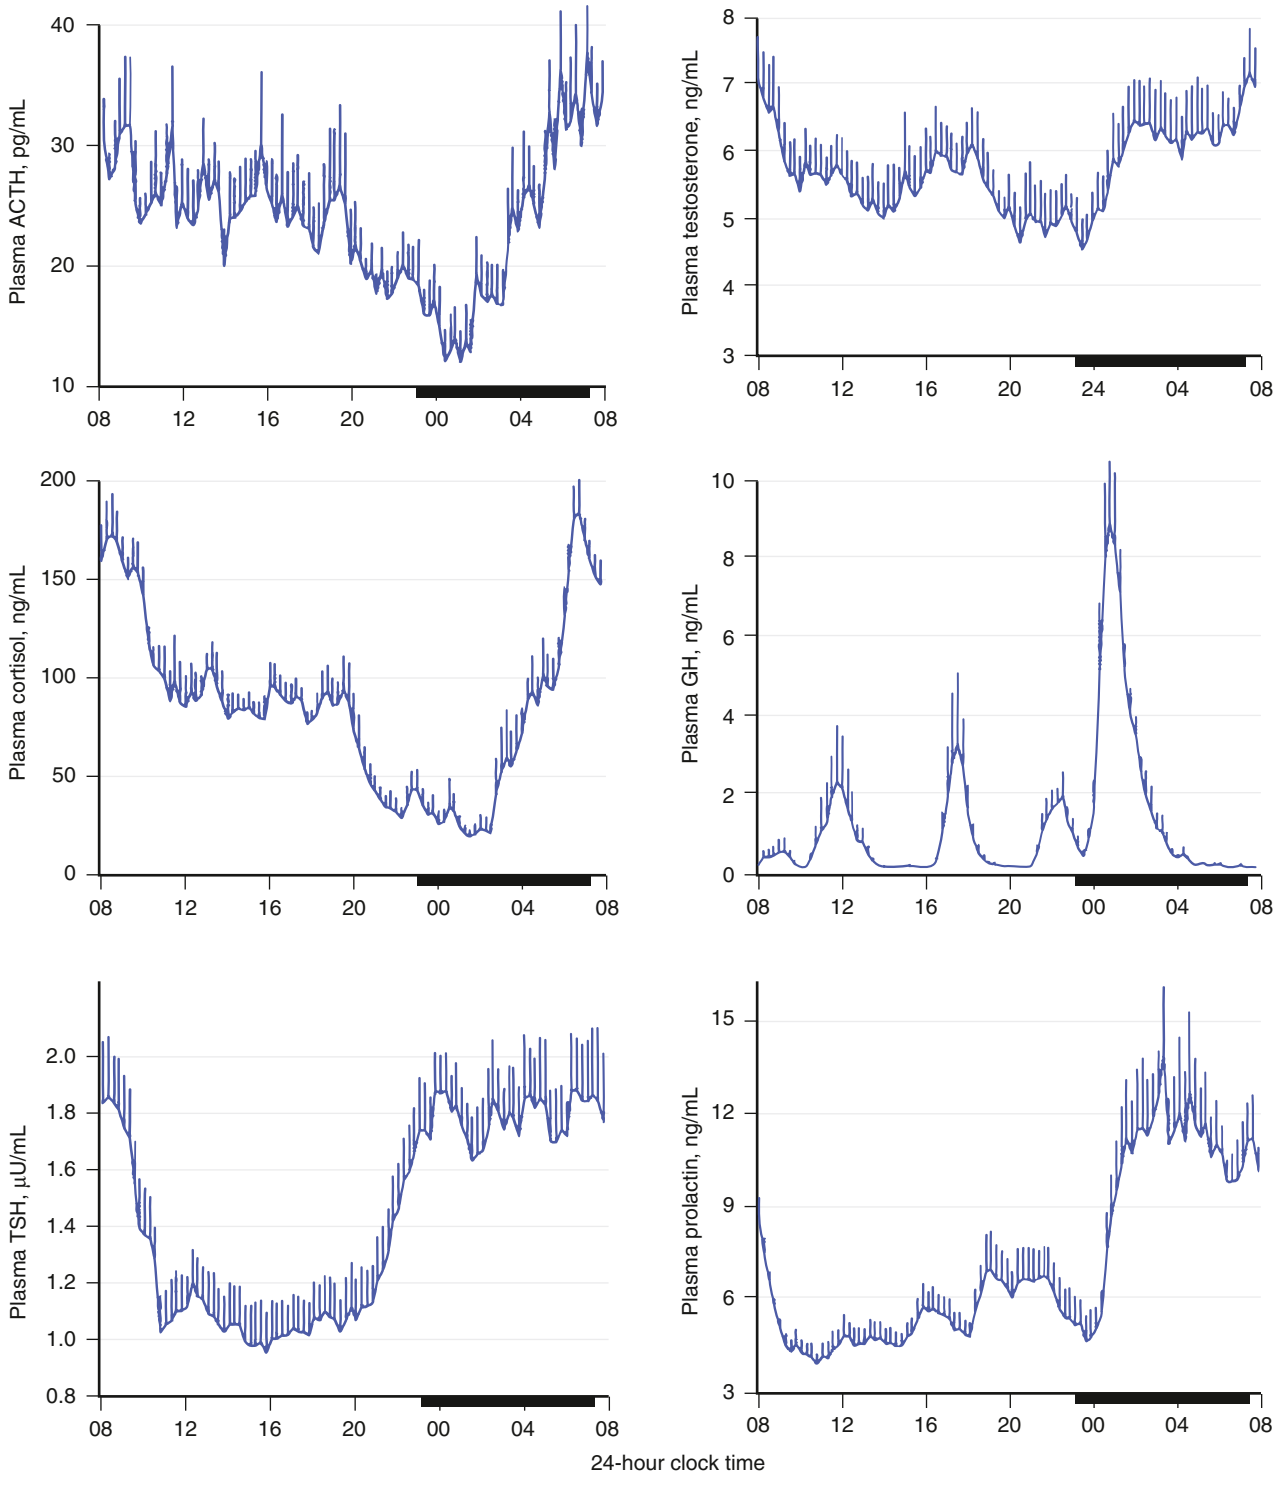
Diseases that cause localized hypothalamic changes include generalized central nervous system diseases (e.g., neurosarcoidosis [Chapter 83]) and processes (e.g., hydrocephalus) (Table 204-1). Systemic illnesses also can alter hypothalamic regulation.

Axons that project to the median eminence contain the various hypophysiotropic factors that are concentrated in the basal portion of the hypothalamus. Thus, lesions located within this final common pathway can decrease secretion of some or all of the pituitary hormones except prolactin, which may increase because its tonic inhibition by dopamine is eliminated. Diabetes insipidus (Chapter 206) may also occur. Symptoms of hypothalamic dysfunction also correlate with the size of the lesion, the involved area of the hypothalamus, and the rapidity at which the lesion grows. Slowly growing lesions typically cause gradual hormone dysregulation rather than sudden symptoms. However, slowly growing but large lesions also can cause acute symptoms if a slight increment in growth eliminates the remaining vestiges of vasopressin or ACTH secretion. The best way to diagnose structural hypothalamic lesions is magnetic resonance imaging (MRI) with gadolinium enhancement, although computed tomographic (CT) scanning with intravenous contrast is also effective. Visual field testing may detect an impingement on the optic chiasm and nerves by hypothalamic lesions. Detailed hypothalamic-pituitary function testing may reveal functional hypothalamic disruption that is not otherwise clinically evident.

CONGENITAL EMBRYOPATHIC DISORDERS

The most common embryopathic disorders that affect the hypothalamus are the midline cleft syndromes, which cause varying defects of midline structures, especially the optic and olfactory tracts, the septum pellucidum, the corpus callosum, the anterior commissure, the hypothalamus, and the pituitary. The clinical features of midline cleft defects vary from cyclopia to cleft lip and from isolated hypothalamic hormone defects to panhypopituitarism.

Optic nerve hypoplasia involves a spectrum of anatomic malformations and clinical manifestations ranging from isolated hypoplasia of one or both optic nerves, with a variable degree of visual impairment, to extensive brain malformations, hypothalamic-pituitary dysfunction, neurocognitive disability, and autism spectrum disorders (Chapter 385). It is the second leading cause



E-FIGURE 204-1. Hormonal circadian rhythms. Mean (+SEM) profiles of plasma levels of adrenocorticotropic hormone (ACTH), cortisol, thyroid-stimulating hormone (TSH), testosterone, growth hormone (GH), and prolactin from a group of 8 to 12 normal men studied at 15-minute intervals for 24 hours. The sleep times are indicated by black bars. (Redrawn with permission from Van Cauter E. Diurnal and ultradian rhythms in human endocrine function: a minireview. *Horm Res*. 1990;34:45-53.)

TABLE 204-1 ETIOLOGY OF HYPOTHALAMIC DISEASE BY AGE OF PRESENTATION

NEONATES
Congenital embryopathic disorders: agenesis of the corpus callosum, cleft palate (*HESX1*)
Congenital disorders: isolated hormone and receptor mutations, combined pituitary hormone deficiency (*PIT1, PROP1*), Laurence-Moon-Bardet-Biedl syndrome, Prader-Labhart-Willi syndrome
Tumors: glioma, hemangioma
Trauma
Hydrocephalus, hydranencephaly, kernicterus
1 MONTH TO 2 YEARS
Tumors: glioma, especially optic glioma, hemangiomas
Infiltrative disease: Langerhans cell histiocytosis, meningitis
Hydrocephalus
2-10 YEARS
Tumors: craniopharyngioma, glioma, dysgerminoma, hamartoma, leukemia, ganglioneuroma, ependymoma, medulloblastoma
Infiltrative disease: Langerhans cell histiocytosis, meningitis, tuberculosis, encephalitis
Irradiation: for nasopharyngeal tumors, intracranial tumors, leukemia
Functional: psychosocial deprivation
10-25 YEARS
Congenital disorders: Kallmann syndrome, gonadotropin-releasing hormone receptor defects
Tumors: craniopharyngioma, pituitary tumors, glioma, hamartoma, dysgerminoma, dermoid, lipoma, neuroblastoma
Trauma: subarachnoid hemorrhage, vascular aneurysm, arteriovenous malformation
Infiltrative diseases: Langerhans cell histiocytosis, sarcoidosis, tuberculosis, meningitis, encephalitis, leukemia
Chronic hydrocephalus or increased intracranial pressure
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
25-50 YEARS
Tumors: pituitary tumors, meningioma, craniopharyngioma, Rathke cleft cyst, glioma, lymphoma, angioma, colloid cysts, ependymoma
Infiltrative diseases: sarcoidosis, Langerhans cell histiocytosis, tuberculosis, viral encephalitis
Subarachnoid hemorrhage, vascular aneurysms, arteriovenous malformation
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Nutritional: Wernicke disease
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
50 YEARS AND OLDER
Tumors: pituitary tumors, meningioma, craniopharyngioma, sarcoma, glioblastoma, lymphoma, colloid cysts, ependymoma
Vascular: infarct, subarachnoid hemorrhage, pituitary apoplexy, aneurysm
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Infiltrative diseases: encephalitis, sarcoidosis, meningitis
Nutritional: Wernicke disease

Modified from Plum F, Van Uitert R. Non-endocrine diseases of the hypothalamus. In: Reichlin S, Baldessarini RJ, Martin JB, eds. *The Hypothalamus*. New York: Raven Press; 1978:415.

of congenital visual impairment, superseded only by cortical visual impairment. Some such patients have precocious puberty (Chapter 214), presumably because they lack other inhibitory influences but have intact GnRH-producing structures.

Nearly 50% of patients with "idiopathic" growth hormone deficiency will have an absent infundibulum detectable on MRI. Mutations in *HESX1*, *SOX2*, *SOX3*, and *OTX2* transcription factor genes cause agenesis of the corpus callosum and panhypopituitarism. The diagnosis is made by finding anosmia and low gonadotropin levels, and MRI will show absence or hypoplasia of the olfactory bulbs.

TUMORS

The most common tumors that affect the hypothalamus are pituitary adenomas with significant suprasellar extension. Such tumors typically either disturb the pituitary stalk and the mediobasal hypothalamus or compress the normal pituitary.[4]

Tumors cause symptoms because their mass effects precipitate headache, vomiting, visual disturbance, seizures, hypopituitarism, and polyuria. Some patients have galactorrhea, amenorrhea, and hyperprolactinemia suggestive of a prolactinoma. Careful endocrine testing reveals varying degrees of hypopituitarism in 50 to 75% of cases, modest hyperprolactinemia in 25 to 50%, and often diabetes insipidus. A normal or elevated prolactin level indicates the hypothalamus or stalk as the site of the lesion, and normal pituitary function often returns following therapy. Diabetes insipidus (Chapter 206) is rarely caused by pituitary adenomas.

Craniopharyngiomas, which arise from remnants of the Rathke pouch, are the next most common tumors affecting the hypothalamus. Microscopically, craniopharyngiomas consist of cysts alternating with stratified squamous epithelium. The cyst's fluid is usually dark and thick, and the lesion is often calcified. A Rathke cleft cyst is a closely related lesion that develops from the space between the anterior and rudimentary intermediate lobes. These cysts are lined with cuboidal (as opposed to squamous) epithelium, and their fluid is usually white and mucoid. Craniopharyngiomas most commonly arise during childhood but can occur in adults and even the elderly.[5]

Transsphenoidal surgery is the preferred treatment if the hypothalamus is not involved.[6] Unfortunately, surgical extirpation of craniopharyngiomas commonly worsens pituitary function; often results in complete panhypopituitarism and diabetes insipidus; and may damage the hypothalamic centers that regulate thirst, body temperature, and food intake, thereby resulting in severe obesity.[7] Hypothalamic-sparing surgery may cause less obesity without increasing recurrence rates. If a craniopharyngioma cannot be removed completely, postoperative radiation reduces the risk of recurrent symptoms. Rathke cleft cysts are less likely to recur.

Suprasellar dysgerminomas[8] arise from primitive germ cells, which are structurally identical to germ cell tumors and which migrated during fetal development. The tumors occur most commonly in children, in whom they decrease growth because of hypopituitarism, and also cause diabetes insipidus and visual problems. Hyperprolactinemia occurs in more than 50% of affected children, and 10% have precocious puberty because of the production of human chorionic gonadotropin (HCG) by the tumor. The finding of an elevated HCG level in the spinal fluid may be diagnostic. As compared with craniopharyngiomas, these tumors are very radiosensitive, and radiation therapy combined with chemotherapy is the preferred treatment.

A hypothalamic hamartoma[9] is a nodule of hypothalamic neurons, glia, and fiber bundles. It is attached to the hypothalamus by a pedicle between the tuber cinereum and the mammillary bodies, and it extends into the basal cistern. Asymptomatic hamartomas can be identified in up to 20% of routine autopsies. These lesions rarely may enlarge and disrupt hypothalamic function because they compress adjacent tissues. Less commonly, they may cause seizures, especially gelastic seizures. Some hamartomas can be associated with other congenital anomalies and mutations in the transcription factor gene *GLI3*. A choristoma (or gangliocytoma) is a hamartomatous variant composed of similar tissue in the anterior pituitary but not attached to the hypothalamus. These neuronal tumors cause precocious puberty, acromegaly, or Cushing syndrome when they produce GnRH. Surgery can be risky. Treatment with a long-acting GnRH analogue can be used to suppress gonadotropin secretion and may be preferred if the hamartoma does not cause mass effects.

Other tumors and space-occupying lesions in the suprasellar area include arachnoid cysts, meningiomas (Chapter 175), gliomas (Chapter 175), astrocytomas, chordomas, infundibulomas, cholesteatomas (Chapter 396), neurofibromas (Chapter 385), lipomas, and metastatic cancer (especially from the breast and lung). Such lesions can cause varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia. Unfortunately, surgical therapy often worsens the hormonal deficit and may cause other hypothalamic damage.

INFLAMMATORY AND INFILTRATIVE DISORDERS

Sarcoidosis (Chapter 83) involves the central nervous system clinically in 1 to 5% of patients and in up to 16% of patients at autopsy. Isolated central nervous system sarcoidosis, however, is uncommon. When sarcoidosis involves the central nervous system, it affects the hypothalamus in 10 to 20% of cases. Sarcoid granulomas can be seen in the hypothalamus, pituitary, or stalk, either as an infiltrative process or as a mass lesion.[10] The most common endocrinologic sequelae are varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia. Obesity can also result from hypothalamic involvement by sarcoidosis. Examination of cerebrospinal fluid usually shows pleocytosis, elevated protein levels, low glucose levels, and variable elevations of angiotensin-converting enzyme. In a patient who has isolated central nervous system sarcoidosis, the diagnosis may be extremely difficult to establish, and biopsy

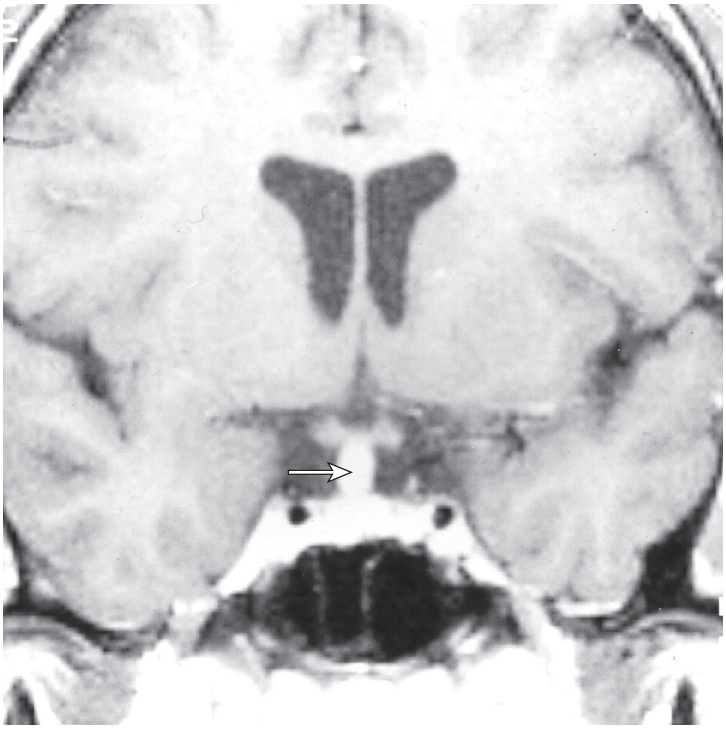


FIGURE 204-3. Thickened pituitary stalk in Langerhans cell histiocytosis. Magnetic resonance image of patient with Langerhans cell histiocytosis who manifested initially with amenorrhea, galactorrhea, and diabetes insipidus. *Arrow* points to the thickened pituitary stalk. (Reproduced with permission from Purdy LP, Molitch ME. Sudden onset of diabetes insipidus in an adolescent. *Endocr Trends*. 1998;5:1-7.)

is often required. Corticosteroid therapy can at least partially reverse the thirst disorders, but deficits in anterior pituitary hormones usually do not improve.

Langerhans cell histiocytosis (Chapter 155) of the hypothalamus can cause diabetes insipidus, varying degrees of hypopituitarism, and hyperprolactinemia.[11] It is the most common cause of diabetes insipidus in children. This infiltration usually thickens the pituitary stalk, but it may cause a mass lesion of the hypothalamus or pituitary (Fig. 204-3). Osteolytic lesions may be seen on radiographs of the jaw or mastoid. Therapy consists of surgery, focal irradiation, or chemotherapy with alkylating agents and high-dose corticosteroids.

Other infiltrative diseases that can cause progressive alteration in the hypothalamic regulation of the secretion of pituitary hormones include tuberculosis (Chapter 299), lymphomas (Chapters 171 and 172), and fungal diseases.

VASCULAR DISEASE

An enlarging aneurysm (Chapter 377) may present as a mass lesion in the hypothalamic-pituitary area, where it can cause visual field defects and hypopituitarism. Tumors and aneurysms may also coexist, and careful MRI evaluation is critical. Vascular infarction very rarely causes hypothalamic disease, but almost 50% of cases of subarachnoid hemorrhage (Chapter 377) may be associated with varying degrees of hypopituitarism. Diabetes insipidus is an uncommon complication.

TRAUMA

Traumatic brain injury (Chapter 368) can cause a variety of hormonal perturbations that range from isolated ACTH deficiency to panhypopituitarism with diabetes insipidus.[12] With frontal injuries, the brain travels backward, but the pituitary cannot move; as a result, the pituitary stalk is avulsed, with interruption of the portal vessels. The paraventricular and supraoptic nuclei and median eminence are particularly involved with microhemorrhages, hence the high frequency of panhypopituitarism with diabetes insipidus. Most patients with head injury are hyperprolactinemic, which clinically confirms that the primary site of injury is the hypothalamus or stalk. Blood levels of growth hormone, ACTH, TSH, LH, and prolactin may actually be elevated. These levels subsequently fall, and then pituitary function either may return to normal or hypopituitarism may develop.[13] Overall, about 25% of surviving patients develop hypopituitarism after major traumatic brain injury, but significant hypothalamic, pituitary stalk, or anterior pituitary damage is seen in about 85% of fatal cases. Deficiencies in ACTH (and hence cortisol) may be life-threatening, so cortisol levels should be monitored carefully in the hours and days after major brain trauma. Hypocortisolism must be treated with stress doses of glucocorticoids (Chapter 28). However, hypopituitarism should not be confused with prolonged stress-related endocrine alterations.

IRRADIATION

Whole-brain irradiation frequently causes hypothalamic dysfunction, with resulting endocrine abnormalities and behavioral changes. The loss of pituitary function is so frequent that all patients who have had their pituitary and hypothalamic areas irradiated must be monitored periodically to detect the most common abnormality, which is hyperprolactinemia, as well as hypopituitarism that occurs, especially when the radiotherapy is targeted to the hypothalamic area.[14] However, such deficiencies may occur many years later, so annual testing is recommended for up to 20 years. Stereotactic gamma knife irradiation and external beam radiation of pituitary and other parasellar tumors appear to carry a similar risk of subsequent hypopituitarism.

EFFECTS OF HYPOTHALAMIC DISEASE ON PITUITARY FUNCTION

Hypothalamic disease can cause both pituitary hyperfunction and hypofunction of varying degrees of severity. Although severe disease can cause absolute deficiencies of the various hormones, milder disease may cause subtle alterations, such as the loss of menstrual cycling and subsequent "hypothalamic" amenorrhea (Chapter 218). Furthermore, these hypothalamic defects may be interrelated. A rather common phenomenon is when hyperprolactinemia owing to hypothalamic dysfunction causes a hypogonadotropic hypogonadism that can be reversed when the elevated prolactin levels are normalized. Oftentimes MRI does not reveal a structural lesion, so a functional defect is presumably related to altered neurotransmitter regulation.

GROWTH HORMONE

Loss of normal secretion of growth hormone is the most common hormonal defect caused by structural hypothalamic disease. About 75% of patients with congenital idiopathic growth hormone deficiency respond normally to exogenous GHRH, thereby implying that the problem is probably disordered hypothalamic regulation (Chapter 205). A rare form of growth hormone deficiency is caused by a mutation in the GHRH receptor. Reversible idiopathic growth hormone deficiency, which can be caused by inadequate parental care and affection, is termed emotional deprivation syndrome or psychosocial dwarfism. The disordered regulation of growth hormone is probably caused by psychogenic alterations in the balance of neurotransmitters needed for normal secretion of GHRH and somatostatin. Restoration of proper care promptly normalizes the secretion of growth hormone and subsequent growth. Treatment of systemic illnesses that also may decrease the secretion of growth hormone will correct the growth abnormality.

GONADOTROPINS

Hypothalamic Hypogonadism

The primary defect in hypothalamic hypogonadism (Chapter 216) is when the diminished secretion of GnRH impairs the secretion of pituitary gonadotropin and gonadal function.[15] The cause may be congenital or acquired. Depending on the age of onset, these conditions may be manifested as either delayed development or loss of adult gonadal function. Hormonal deficiencies may be isolated to GnRH or involve other hormones as well. Primary growth hormone deficiency is the most common cause. Hypothalamic structural damage is the second most common cause, but a substantial portion of these defects are caused by hyperprolactinemia and are reversible if the hyperprolactinemia is corrected.

In children with isolated disorders of GnRH and gonadotropins, growth and development are normal until puberty, when the expected growth spurt does not occur. About 50% of males with GnRH deficiency have undescended testes, probably secondary to the absence of gonadotropins during fetal development. The most common congenital lesion causing prepubertal GnRH deficiency is Kallmann syndrome. In patients with GnRH deficiency, subcutaneous replacement of GnRH every 2 hours via a portable pump (beginning with a dose of 25 ng/kg per bolus and adjusting upward until there is a rapid increase of FSH and LH so that testosterone levels rise to normal) restores

normal spermatogenesis. Similar approaches in women restore the ovulatory cycles in 80% of patients. In men, comparable results can be obtained with a more practical administration of human chorionic gonadotropin (2000 units 3 times per week subcutaneously under the abdominal skin or intramuscularly into the buttocks) to normalize the serum testosterone within 1 to 2 months. In patients with GnRH receptor mutations, GnRH therapy is not successful; testosterone replacement (intramuscular testosterone cypionate 100 to 200 mg every 2 weeks or 50 to 100 mg every week; or topical gel 1% or 1.62% 50 to 100 mg daily) alone induces adequate androgenization but does not increase testicular size or generate spermatogenesis.[16]

Acquired loss of previously normal GnRH secretion in adulthood may be caused by structural hypothalamic damage (e.g., a tumor), a functional change without a detectable anatomic lesion, or hyperprolactinemia. A CT or MRI is indicated to evaluate possible structural disease. Most cases of functional hypogonadotropic hypogonadism occur in women, especially related to weight loss, excessive exercise with reduced body fat even if body weight is unchanged, psychogenic stress, or systemic illness, but idiopathic forms also are seen. Pulsatile gonadotropin secretion is usually lost, but the gonadotropin response to injected GnRH is normal. Weight gain and reduced exercise can restore normal gonadal function. Furthermore, experimental leptin administration may also restore the normal pulsatile secretion of gonadotropins and subsequent ovulation, thereby confirming that leptin has a critical mediating influence on reproductive function. Postpuberty hyperprolactinemia can also decrease GnRH as well as the pulsatile secretion of LH and FSH, thereby resulting in anovulation with oligomenorrhea and amenorrhea in women and impotence and infertility in men.

In the idiopathic form, spontaneous resolution does not occur. The treatment of idiopathic functional hypogonadotropic amenorrhea focuses on restoration of a normal estrogen status to promote well-being, to prevent osteoporosis, and to facilitate ovulation. The first two usually can be achieved with cyclic estrogen and progesterone (Chapter 218), whereas the latter may require clomiphene, GnRH, or gonadotropin therapy. In men, similar goals may be achieved with testosterone, GnRH, or gonadotropins (see Chapter 216).

Hypothalamic Hypergonadism (Precocious Puberty)

Precocious puberty (Chapter 217) is defined when puberty begins before 8 years of age in girls or 9 years of age in boys.[17] Central (GnRH-dependent) precocious puberty is characterized by hormonal changes similar to what occurs at the time of normal puberty (i.e., an increase in the pulsatile release of LH, an increase in the gonadotropin response to GnRH, and an increase in gonadal steroid secretion). Pseudoprecocious puberty results from peripheral (gonadal or adrenal) causes.[18]

In girls, hypothalamic hamartomas account for only about 15% of cases, other central nervous system lesions for 14%, and McCune-Albright syndrome (polyostotic fibrous dysplasia [Chapter 212]) for 6%; the remaining 65% are idiopathic. GnRH-dependent precocious puberty can be related to premature activation of the GnRH pulse generator by a variety of lesions, or it may also be idiopathic.

Boys represent only about 10% of cases of central precocious puberty, but they often have more serious underlying causes (Chapter 216). For example, hypothalamic hamartomas account for about 40% of boys who have central GnRH-dependent precocious puberty, another 30% are caused by central nervous system lesions, familial disease accounts for about 25% of cases, and the remainder are idiopathic.

The treatment of central GnRH-dependent precocious puberty emphasizes surgical removal of the tumor or medical therapy with a long-acting GnRH analogue, either as monthly injections or yearly implants (see Chapters 216 and 217). When therapy is discontinued at the time of normal puberty, sex steroid levels increase, secondary sexual characteristics again develop, growth increases, and regular menses appear spontaneously.

PROLACTIN

Hypothalamic Hyperprolactinemia

Structural or infiltrative hypothalamic lesions can decrease how much dopamine reaches the lactotrophs and thereby cause modest hyperprolactinemia (usually <100 ng/mL). A nonsecreting pituitary adenoma with extensive suprasellar extension can cause elevated prolactin levels that must be distinguished from a prolactin-secreting adenoma, which usually elevates prolactin levels 5 to 50 times higher (Chapter 205). In patients with very large tumors, the prolactin level should be measured undiluted and at 1 : 100 dilution to avoid spurious findings. A number of medications, especially antipsychotic agents, can cause hyperprolactinemia, primarily by interfering with central catecholamines.

THYROID-STIMULATING AND ADRENOCORTICOTROPIC HORMONE

Hypothalamic hypothyroidism (Chapter 207) is caused by a central lesion that impairs the secretion of TRH, usually along with the loss of other hormones.[19] It occurs considerably less commonly than hypothalamic deficiencies in growth hormone and gonadotropins. Molecular causes of central hypothyroidism include mutations in the TRH receptor and the TSH beta gene that encodes for the TSH β-glycoprotein. In these patients, TSH is less biologically active than normal, so it binds less well to the TSH receptor. Treatment is with L-thyroxine (Chapter 207), and patients should be monitored with free thyroxine (T_4) levels rather than TSH levels.

Hypothalamic lesions rarely cause ACTH deficiency.

EFFECTS OF HYPOTHALAMIC DISEASE ON OTHER NEUROMETABOLIC FUNCTIONS

Other functions that are regulated, at least in part by the hypothalamus include food intake, carbohydrate metabolism, temperature control, sleep, and behavior.

ALTERATIONS IN FOOD INTAKE

Hypothalamic Obesity

Destruction of the mediobasal hypothalamus can suppress the phenomenon of satiety, thereby resulting in hyperphagia and hypothalamic obesity.[20] Because of the location of the lesions, hypopituitarism and diabetes insipidus often coexist. Whether the obesity seen in rare patients with Prader-Willi (Chapter 214) and Laurence-Moon-Biedl-Bardet (Chapter 214) syndromes is caused by hypothalamic dysfunction is unproven.

Hypothalamic Anorexia

Very rare bilateral lesions of the lateral hypothalamus can destroy nigrostriatal dopaminergic fibers that pass through this area, suppress appetite, increase peripheral norepinephrine turnover, and raise the metabolic rate. By comparison, the hormonal changes seen in patients with anorexia nervosa (Chapter 200) are a result of the weight loss, with no evidence for a primary preexisting hypothalamic abnormality.

HYPERGLYCEMIA

The hypothalamic response to stress can release growth hormone, ACTH, and prolactin, which then stimulate gluconeogenesis, lipolysis, and insulin resistance, thereby resulting in elevation of blood glucose levels. This hypothalamic response also activates the sympathetic nervous system, which releases catecholamines that inhibit insulin secretion and stimulate glycogenolysis.

TEMPERATURE REGULATION

Although input regarding body temperature comes from a variety of feedback signals,[21] these signals appear to converge on a common set of neurons in the preoptic area of the hypothalamus. The anterior hypothalamus and preoptic area contain temperature-sensitive neurons that respond to internal temperature changes by initiating the thermoregulatory responses that are needed to restore and maintain a constant temperature. Measures that dissipate heat include cutaneous vasodilation, sweating, and panting; measures that increase body heat include increasing metabolic heat production, shivering, and cutaneous vasoconstriction.

Poikilothermy results from an inability to dissipate or generate heat to keep the body temperature constant in the face of varying ambient temperatures. This condition results from bilateral lesions, possibly due to ischemia, in the posterior hypothalamus and rostral mesencephalon, which are the areas responsible for the final integration of thermoregulatory neural efferents. Patients with this condition are not bothered by temperature changes and typically are unaware that they have such a problem. Depending on the ambient temperature, they may experience life-threatening hypothermia or hyperthermia.

205 ANTERIOR PITUITARY

ROY E. WEISS

DEFINITION

The pituitary is located in the sella turcica, which is a part of the sphenoid bone of the skull. It is attached to the base of the brain by a stalk, known as the infundibulum, and is contained in a capsule that is continuous with the dura mater, thereby placing it technically outside of the blood-brain barrier. The gland itself is composed of two parts, the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). The adenohypophysis has three anatomic components: the pars distalis (where the hormone-secreting cells are situated); the pars tuberalis (which hugs the infundibulum); and the pars intermedia, which is present in children but essentially absent in adulthood. The infundibulum has direct neural fibers that connect to the neurohypophysis, and, in a network of blood vessels, the infundibulum communicates with the adenohypophysis. The inferior border of the pituitary rests on the floor of the sella turcica, and the superior border is located just under the optic chiasm. Growth of the pituitary inferiorly can lead to erosion of the floor of the sella turcica and invasion into the sphenoid bone and sphenoid sinus, whereas the cavernous sinus and carotids are found laterally. Abnormal superior growth of the pituitary explains the visual problems encountered when the pituitary is enlarged by tumor, bleeding, or infiltration because of impingement on the optic chiasm.

The superior and inferior hypophyseal arteries provide the main arterial supply to the anterior and posterior pituitary, respectively (Fig. 205-1). These vessels are branches from the internal carotid arteries. The superior hypophyseal artery forms the primary plexus of the hypophyseal portal system at the origin of the infundibulum. Blood from this plexus flows down the portal vessels. The pars distalis receives very little blood from the internal carotid and instead is mainly supplied by the venous system—long portal veins from the plexus and from the neurohypophysis through short portal vessels. This anatomy allows the pars distalis to be exposed to hormones from the hypothalamus, posterior pituitary, and the general blood circulation. Lack of direct arterial supply to the pars distalis makes it vulnerable to ischemia secondary to hypovolemia and hypotension. For the anterior pituitary, venous drainage is by the hypophyseal veins; for the posterior pituitary, it is via the short portal and hypophyseal veins to the cavernous sinus. The cavernous sinus drains into the inferior petrosal sinuses and then the internal jugular vein.

PATHOBIOLOGY

The Pituitary Axis

The pituitary gland secretes adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and growth hormone, largely regulated by signals from the hypothalamus (Chapter 204), and it also secretes prolactin, largely regulated by dopamine as well as by thyrotropin-releasing hormone (see Fig. 205-1). The multitude of effects that the hormones of the pituitary have on the physiology and metabolism of the entire body provides exquisite control of hormone secretion regulated via multiple feedback loops and stimuli, not only from the hypothalamus, but also from higher in the brain and in the environment. All pituitary hormones are regulated and secreted with a highly reproducible diurnal variation and with superimposed episodic secretion throughout the day and night and influenced by sleep and wakefulness (Chapter 204). Therefore, measurement of hormone levels must account for the episodic secretion of the hormones, and a single point in time may not reflect the overall activity of the axis. For example, the stress and pain (although minimal) of phlebotomy itself can be sufficient to cause an increase in prolactin and cortisol.

One example of axis regulation is the release of thyroid hormone from the thyroid under the control of thyroid-stimulating hormone from the pituitary thyrotrophs. The more TSH stimulates the TSH receptors on the thyroid cells (thyrocytes), the more thyroid hormone is released. The thyroid hormone then feeds back to the pituitary to downregulate further secretion of TSH, which then turns off thyroid hormone release from the thyrocytes. Superimposed on this process is the hypothalamus, which secretes TRH (thyrotropin-releasing hormone) and stimulates the release of TSH. However, thyroid hormone also provides feedback to the hypothalamus and, independent of TSH, turns off TRH secretion. Therefore the pituitary's thyrotrophs need to integrate the positive stimulation of TRH and at the same time the inhibition by the thyroid hormone levels in order to modulate the level of TSH release. The story is still not complete, because dopamine and other neurotransmitters from centers in the brain above the hypothalamus can stimulate and inhibit TRH, thereby providing an additional level of control over thyroid hormone secretion. Similar multilevel feedback control mechanisms can be described for cortisol from the adrenal gland as well as other pituitary hormones such as the gonadotropins, prolactin, and growth hormone. Understanding the basis for hypothalamic-pituitary-target endocrine gland axis regulation is essential for the diagnosis of abnormalities at specific levels of the axis as interpreted from provocative and suppressive tests used clinically to assess the pituitary axes.

HYPOPITUITARISM

EPIDEMIOLOGY AND PATHOBIOLOGY

Hypopituitarism is a deficiency of one or more pituitary hormones. The prevalence is between 290 and 455 cases per million, with an incidence of 42 cases per million per year. Hypopituitarism can be congenital (with known and unknown genetic causes)[1] and acquired (Table 205-1).[2] Panhypopituitarism refers to a defect in all pituitary hormone lines.

The most common cause of hypopituitarism is a tumor, specifically a macroadenoma in the sella. Tumor enlargement within the confines of the bony sella turcica can compress the normal pituitary cells, thereby resulting in their failure to function. Irradiation of the pituitary, pituitary infarction (such as

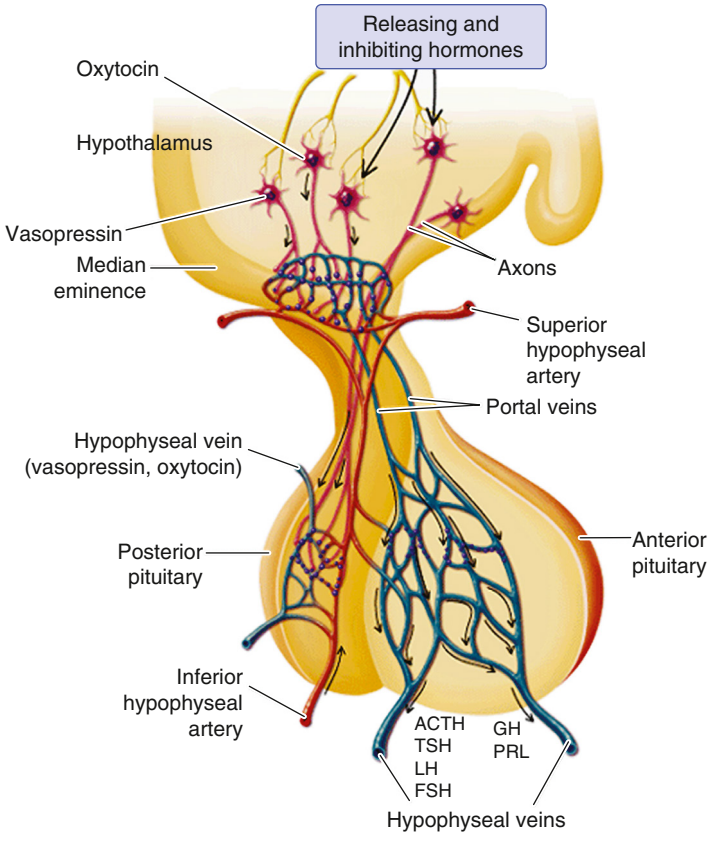

FIGURE 205-1. Structural-functional, humoral, endocrine, and neuroendocrine relationships within the hypothalamic-pituitary unit emphasize the unique and intimate interdependence of neural structures and hormone secretion with the circulation. Oxytocin and vasopressin neuron bodies located in the hypothalamus send axons through the pituitary stalk that terminate in the posterior pituitary, where they release oxytocin and vasopressin into blood vessels within the posterior pituitary. Hypothalamic neurons that produce growth hormone–releasing hormone, corticotropin-releasing hormone, thyrotropin-releasing hormone, and gonadotropin-releasing hormone send their axons through the median eminence to terminate and release their hormones into the hypophyseal-portal circulation. This network of blood vessels is located at the median eminence, which surrounds the pituitary stalk and penetrates into the anterior lobe of the pituitary. These hypothalamic neurohormones stimulate responsive anterior pituitary cells to secrete growth hormone (GH), adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH), respectively. Dopamine neurons reaching the median eminence are responsible for tonic inhibition of prolactin (PRL) secretion from the anterior pituitary, whereas somatostatin released from somatostatinergic neurons inhibits the release of GH and thyrotropin-releasing hormone. (From Melmed S. *The Pituitary,* 3rd ed. London: Elsevier; 2011.)

ABSTRACT

The anterior pituitary, which is the command center for the majority of endocrine organs, regulates the adrenal, thyroid, and gonads as well as being responsible for the release of growth hormone and prolactin. Diseases of the anterior pituitary can result in abnormally low or high secretion of one or more of the hormones. Diagnosis of these conditions requires astute clinical skills to suspect the syndromes of hormone deficiency or excess, as well as rational provocative testing, based on the physiology, and selective imaging. Treatment either replaces the deficient hormones or uses medical or surgical intervention to correct hypersecretory states.

TABLE 205-1 CONGENITAL AND ACQUIRED CAUSES OF HYPOPITUITARISM

CONGENITAL EMBRYOPATHIC DEFECTS
Anencephaly
Midline cleft defects: septo-optic dysplasia, basal encephalocele, cleft lip and palate
Pituitary aplasia
Kallmann syndrome (GnRH defect with anosmia)
ACQUIRED DEFECTS
Tumors: pituitary adenomas, craniopharyngiomas, dysgerminomas, meningiomas, gliomas, metastatic tumors, hamartomas, Rathke cleft cysts
Irradiation
Trauma: surgery, external blunt trauma (Chapter 368)
Empty sella syndrome
Vascular
Pituitary apoplexy
Sheehan syndrome
Internal carotid aneurysm
Vasculitis (Chapter 249)
Subarachnoid hemorrhage (Chapter 377)
Inflammatory and infiltrative diseases
Sarcoidosis (Chapter 83)
Histiocytosis (Chapter 155)
Tuberculosis (Chapter 299), syphilis (Chapter 295)
Granulomatosis with polyangiitis (Chapter 249)
Meningitis (Chapter 381)
Lymphocytic hypophysitis, infundibulohypophysitis
Metabolic defects
Hemochromatosis (Chapter 196)
Amyloidosis (Chapter 174)
Critical illness (Chapter 88)
Malnutrition (Chapter 197 and 198)
Anorexia nervosa (Chapter 200)
Psychosocial deprivation
Idiopathic

GnRH = gonadotropin-releasing hormone.

Sheehan syndrome, which is caused by severe postpartum bleeding[3]), surgical intrusion, and infiltrative disease also can compromise normal pituitary functioning.

Genetic defects have been reported at every level of the hypothalamic pituitary axis, including defects in the hypothalamic factors, receptors for the hypothalamic factors, and the genes for the pituitary hormones. Defects in the genes coding for the specific hormone almost always result in a low serum concentration of the hormone.

Although congenital hypopituitarism may involve deficiency of a single or multiple pituitary hormones, acquired types of hypopituitarism usually simultaneously involve more than one of the pituitary hormones. Defects in genes encoding for factors such as the *PIT1* and *PROP1* genes may impair pituitary cell differentiation. Furthermore, the pituitary hormone receptor in the respective glands may be defective, thereby resulting in resistance to the action of the pituitary hormones. Finally, genetic defects in the gene coding for the hormone or the hormone's receptor can result in profound hormone deficiency.

Functional causes of defective pituitary function can be seen in severe malnutrition (Chapter 197), in anorexia nervosa (Chapter 200), or in critically ill patients who are in a state of severe calorie deprivation. In these situations, central (hypothalamic and higher) mechanisms and molecular mediators (e.g., cachexins and tumor necrosis factor) inhibit the release of pituitary hormone. This form of hypopituitarism is generally reversible when the caloric situation improves.

Traumatic brain injury (Chapter 368) is an increasingly recognized cause of hypopituitarianism.[4] Deposition and infiltration of amyloid protein in amyloidosis (Chapter 174), iron in hemochromatosis (Chapter 196) or granulomas (in sarcoidosis [Chapter 83], tuberculosis [Chapter 299], or granulomatosis with polyangiitis [Chapter 249]) also can cause hypopituitarism. Invasion of the hypothalamus and pituitary by histiocytosis (Chapter 155) or metasteses from breast cancer, lung cancer, melanoma, and rarely, colon cancer can impair pituitary function. Hypopituitarism is also a rare complication of infection with human immunodeficiency virus (HIV) or severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2).

In addition to congenital and acquired pituitary defects, hypopituitarism may result from a hypothalamic disorder (Chapter 204). Concurrent diabetes insipidus, which is indicative of dysfunction of the posterior pituitary (Chapter 206), usually suggests combined hypothalamic and pituitary defects. Hyperprolactinemia, which suggests interruption of the hypothalamic dopaminergic inhibition of prolactin, also can be a result of hypothalamic defects.

CLINICAL MANIFESTATIONS

Congenital defects are usually noted soon after birth when an absent pituitary hormone results in growth retardation or failure to develop. Patients may also present with congenital failure of a specific pituitary function and manifest with early-onset growth defects, delayed puberty, or hypothyroidism.

Acquired hypopituitarism presents earlier in its course in women of reproductive age because any perturbation in the hypothalamic pituitary milieu will likely result in an abnormality of the menstrual cycle (Chapter 218), which requires orchestration of multiple hormones that are exquisitely sensitive to changes in the pituitary hormones. By comparison, males of all ages and women of postreproductive age usually have hypopituitarism for several years before the diagnosis is made. In such patients, the symptoms can be nondescript (e.g., fatigue, decreased muscle strength and muscle mass, and increased body fat) and not appreciated for many years after the onset of hypopituitarism.

Although growth hormone deficiency can exist in up to 60% of patients with hypopituitarism, such deficiency in an adult is not likely to cause the same remarkable symptoms as the short stature that is seen in children. When multiple hormones are deficient, the manifestations in adulthood may be as subtle as skin changes, decreased sexual functioning, decreased muscle mass, and increased fat mass.

DIAGNOSIS

Diagnosis of hypopituitarism in patients with secreting or nonsecreting pituitary masses usually involves a combination of static and stimulatory blood tests (Table 205-2) beginning with morning fasting level of ACTH, TSH, FSH, LH, growth hormone, and prolactin. If multiple deficiencies are found, panhypopituitarism is likely. Isolated deficiencies in only one pituitary hormone can occur, but if two or more are deficient, it is likely that all are deficient. Testing (Table 205-2) often depends on the age of the patient and the clinical setting. Oftentimes, no single gold-standard test is available for each hormone, so equivocal results on one test may require another test. For example, growth hormone reserve in children is usually best documented with an arginine stimulation test, whereas an insulin tolerance test would be more appropriate in an adult in whom the ACTH axis should be evaluated at the same time. Sometimes multiple tests may be performed if results of one test are equivocal.

The next diagnostic imperative is to image the pituitary to determine the cause. Magnetic resonance imaging (MRI) is the preferred radiologic method for anatomic definition of the pituitary and its surrounding structures. The normal pituitary is less than 1 cm in height, and a small tumor (microadenoma) can be as small as 1 mm, so high-quality imaging is necessary. Sagittal and coronal images are the most useful to obtain (Fig. 205-2). Intravenous contrast can enhance MRI images because normal pituitary generally enhances more than tumors. When the use of a contrast agent is not contraindicated, T2 images may be helpful to distinguish normal pituitary from a tumor (Fig. 205-3). In such cases, helical computed tomography (CT) also can be useful with noncontrast and immediate postcontrast imaging.

TREATMENT

Treatment includes replacement of the deficient hormones (Table 205-3) but also must address the underlying cause (see Table 205-1), such as hypophysitis, empty sella syndrome, pituitary apoplexy, infiltrating diseases, malnutrition, and pituitary tumors.

PRIMARY DISEASES OF THE ANTERIOR PITUITARY

HYPOPHYSITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Inflammation of the pituitary is known as hypophysitis and can be classified clinically as primary hypophysitis when isolated inflammation of the pituitary is not associated with other inflammatory conditions, infections, or medications, including checkpoint inhibitors.[5] Lymphocytic hypophysitis,

TABLE 205-2 TESTS TO DIAGNOSE PITUITARY INSUFFICIENCY

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV, and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and GH.	If hypoglycemia occurs (glucose <40 mg/dL), GH should increase to >5 µg/L*
	Arginine-GHRH test: GHRH 1 µg/kg IV bolus followed by 30-min infusion of L-arginine (0.5 g/kg up to 30 g)	Normal response is GH >4.1 µg/L
	Glucagon test: 1 mg IM with GH measurements at 0, 60, 90, 120, 150, and 180 min	Normal response is GH >3 µg/L
	Arginine-L-DOPA test: L-DOPA 500 mg PO at start of arginine 30 g in 10% solution IV infusion over 30 min, blood sampled at 30, 60, 90, 120 min	Normal response is GH >1.5 µg/L
Adrenocorticotropic hormone (ACTH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV, and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and cortisol.	If hypoglycemia occurs (glucose <40 mg/dL), cortisol should increase by >7 µg/dL or to >20 µg/dL
	CRH test: 1 µg/kg ovine CRH IV at 8 AM, with blood samples drawn at 0, 15, 30, 60, 90, and 120 min for measurement of ACTH and cortisol	In most normal individuals, the basal ACTH increases two- to four-fold and reaches a peak (20-100 pg/mL). ACTH responses may be delayed in cases of hypothalamic dysfunction. Cortisol levels usually reach 20-25 µg/dL
	ACTH stimulation test: $ACTH_{1-24}$ (cosyntropin), 0.25 mg IM or IV. Cortisol is measured at 0, 30, and 60 min.	A normal response is cortisol >18 µg/dL. In suspected hypothalamic-pituitary deficiency, a low-dose (1-µg) test may be more sensitive
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests:* free T_4, free T_3, TSH	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased
Luteinizing hormone (LH), follicle-stimulating hormone (FSH)	*Basal levels of LH, FSH, testosterone, estrogen*	Basal LH and FSH should be increased in postmenopausal women. Low testosterone levels in conjunction with low or low-normal LH and FSH are consistent with gonadotropin deficiency
Prolactin	*Basal level of Prolactin*	The low range of prolactin levels in men and women is not established and depends on the assay. If prolactin is undetectable, deficiency is likely. Levels lower than 10 ng/mL indicate a possible deficiency

*Values are with polyclonal assays.
ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone–releasing hormone; IM = intramuscularly; IV = intravenously; LH = leutinizing hormone; PO = orally; T_3 = triiodothyronine; T_4 = thyroxine; TSH = thyroid-stimulating hormone.

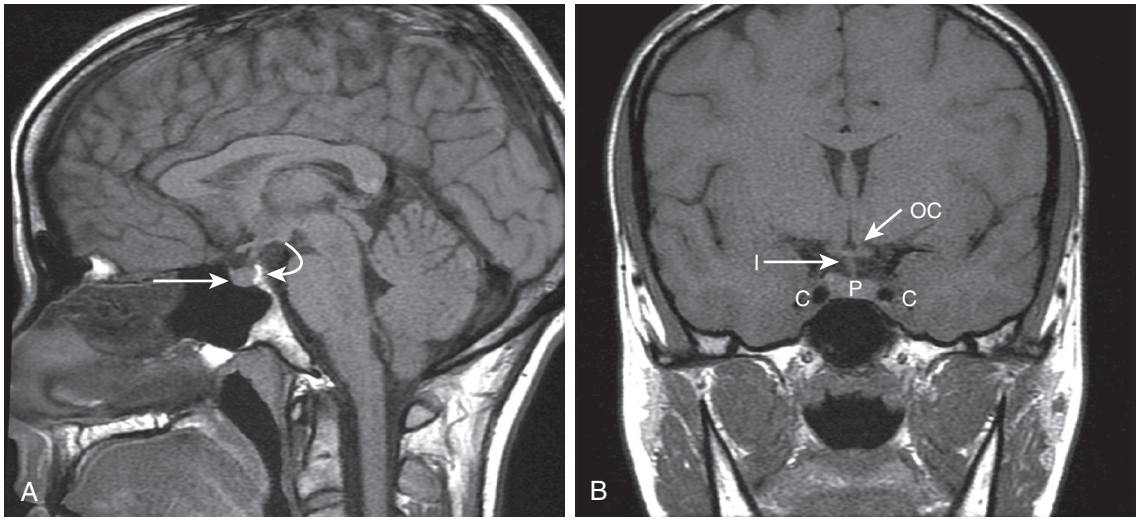

FIGURE 205-2. Magnetic resonance image of normal pituitary. A, Sagittal postcontrast. Normal anterior pituitary (*long arrow*), posterior pituitary (*curved arrow*). **B**, Coronal postcontrast image shows homogeneously enhancing gland (P) and stalk (I). Note the carotid arteries (C), easily depicted by their flow voids. Optic chiasm (OC) is the cranial nerves within the cavernous sinuses.

which is the most common form of this rare condition, occurs three times more frequently in women, typically in the fourth decade and often related to the end of pregnancy or the first few months after delivery. Lymphocytic hypophysitis is also seen in about 3 to 8% of patients treated with immune checkpoint inhibitors, specifically with the anti–CTLA-4 class of inhibitors, with peak onset at a median of 2.3 months after starting therapy.[6] The other histologic types, granulomatous and xanthomatous hypophysitis, are not associated with pregnancy although they are more common in females. The least common form, plasmacytic or IgG4-related hypophysitis, occurs in males in a 2:1 ratio, usually presents in the seventh decade, and may include orbital inflammation, hypertrophic pachymeningitis, and central nervous system parenchymal disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with hypophysitis usually present with headaches and multiple deficiencies of anterior pituitary hormones. Diabetes insipidus (Chapter 206) is reported in about 50% of patients, and most have associated mild hyperprolactinemia.

On MRI, hypophysitis usually causes diffuse pituitary enlargement and thickening of the midline stalk, with a normal sellar size, but MRI cannot reliably differentiate hypophysitis from a pituitary adenoma.

Definitive diagnosis is usually made by biopsy. A clinical diagnosis can, however, be inferred based on radiologic and clinical characteristics during or just after pregnancy or if there is a proximal history of use of anti–CTLA-4 agents several months prior to the onset of symptoms (headaches and weakness).

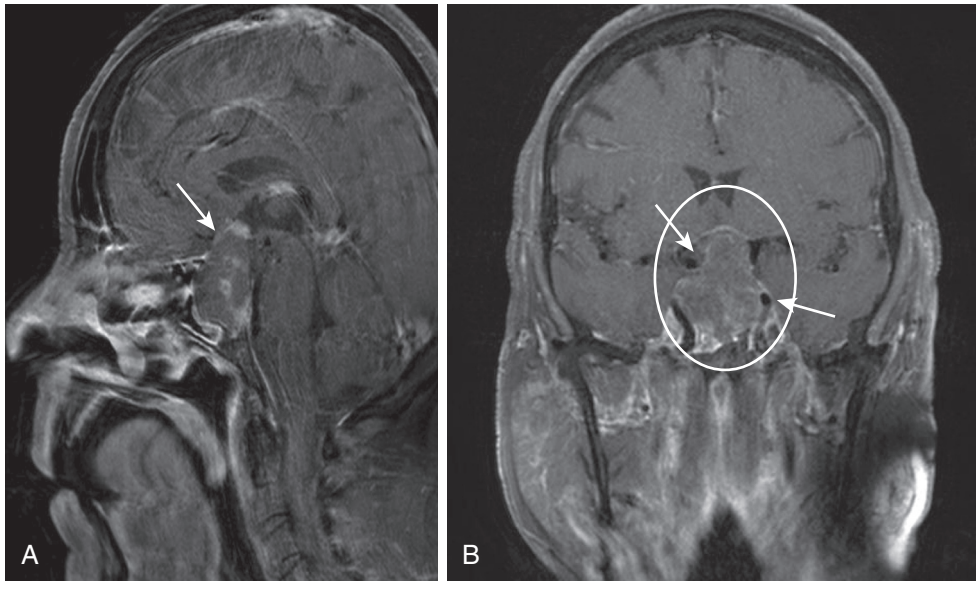

FIGURE 205-3. **Magnetic resonance image of a large pituitary macroadenoma. A**, Sagittal postcontrast. Note the extension of the tumor (*arrow*) below and above the sella. **B**, Coronal postcontrast. Large tumor is encircled with displacement of the carotid arteries (*arrow*), erosion of the floor of the sella turcica, and extension into the sinuses.

TABLE 205-3 HORMONAL REPLACEMENT THERAPY IN HYPOPITUITARISM*

PITUITARY AXIS	HORMONAL REPLACEMENTS
Growth hormone (GH)	In children, GH (0.25 mg/kg) SQ daily. In adults, GH (0.3-1.2 mg) SQ daily. Titrate dose to achieve IGF-I levels in middle to upper part of normal range. Women receiving oral estrogens require higher doses.
Prolactin	None; although not clinically available, human recombinant prolactin has been used
Adrenocorticotropic hormone–cortisol	Hydrocortisone (10-15 mg PO q AM; 5-10 mg PO q PM) or prednisone (2.5 mg PO q AM; 2.5 mg PO q PM). Dose adjusted on clinical basis. Stress dosing: 50-75 mg hydrocortisone IV q8h
Thyroid-stimulating hormone–thyroid	L-thyroxine (0.075-0.15 mg) PO daily
Gonadotropins–gonads	FSH and LH (or HCG) can be used to induce ovulation in women. HCG alone or with FSH can be used to induce spermatogenesis in men. In men, testosterone enanthate (100-300 mg) IM q1-3 wk or testosterone cyclopentylpropionate (100-300 mg) IM q1-3 wk. Testosterone transdermal patches can also be used (5 mg daily). Testosterone gel 5-10 g daily† In women, conjugated estrogens (0.625-1.25 mg) PO days 1-25 each month, cycled with medroxyprogesterone acetate (5-10 mg) PO days 15-25 each month. Low-dose contraceptive pills may also be used. Estrogen-containing transdermal patches are also available.
Posterior pituitary	Desmopressin, 0.05-0.2 mL (5-20 µg) intranasally once or twice daily, or tablets (0.1-0.4 mg q8-12h), or 0.5 mL (2 µg) SQ

*Replacement therapy is dictated by the types of hormone deficiencies and by the clinical circumstances. In each case, the recommended preparations and doses are representative but need to be adjusted for individual patients. Other hormonal preparations are also available.

†Several oral formulations of testosterone undecanoate have recently been approved by the FDA based on single arm trials in hypogonadal men. (https://secure.medicalletter.org/TML-article-1662b.)

FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; HCG = human chorionic gonadotropin; IGF-I = insulin-like growth factor-I; IM = intramuscularly; LH = luteinizing hormone; PO = orally; SQ = subcutaneously.

TREATMENT AND PROGNOSIS

Surgery is indicated when a biopsy is needed for diagnosis or if there is a mass effect. Careful pituitary function testing and repletion of physiologic hormone levels[7] are mandatory, even in patients who do not undergo surgery because they might otherwise die from undiagnosed adrenocortical insufficiency. Stress doses of corticosteroids (e.g., 50 to 75 mg hydrocortisone IV every 8 hours) are indicated perioperatively.

The prognosis is unclear, but both the structural and functional abnormalities can occasionally resolve spontaneously. Glucocorticoids in physiologic doses may have a direct effect on limiting the lymphocytic invasion in lymphocytic hypophysitis, but there are no prospective treatment trials.

TABLE 205-4 PREDISPOSING CONDITIONS ASSOCIATED WITH PITUITARY APOPLEXY

- Infections
  - Dengue fever
  - Hypophysitis
- Radiation therapy
- Diabetes, poorly controlled
- Sickle cell anemia

PITUITARY APOPLEXY

The pituitary can be involved with hemorrhage, infarction, or both. When abrupt, and sometimes catastrophic, hemorrhagic infarction occurs in the pituitary, it is defined as apoplexy.[8]

EPIDEMIOLOGY AND PATHOBIOLOGY

Certain conditions predispose a patient to pituitary apoplexy (Table 205-4). Although all large pituitary tumors are at risk for hemorrhagic infarction, certain functional pituitary tumors, such as those in Cushing disease or acromegaly, may be particularly prone. In women who have microprolactinomas treated with dopamine agonists, stopping the agonist while pregnant can precipitate pituitary apoplexy.[9] Nearly 25% of all patients with apoplexy have inadequately treated hypertension. The main symptoms and consequences of apoplexy are due to the increased pressure present within the bony walls of the sella turcica in which the pituitary resides. A sudden increase in the sellar contents, due to blood and edema, results in increased pressure. This increased pressure and meningeal irritation are responsible for the neurologic symptoms, including the increased pressure in the cavernous sinus and the cranial nerve palsies, as well as bitemporal hemianopsia. Extravasation of blood into the subarachnoid space causes meningeal irritation. Asymptomatic hemorrhage and infarction into a pituitary tumor can occur in 10 to 25% of patients, but true apoplexy occurs in only 2 to 10% of pituitary tumor patients.

CLINICAL MANIFESTATIONS

The most common presenting complaint, headache, can present variably from retro-orbital to unilateral to bilateral temporal headaches during the acute phase of apoplexy. The constellation of headache, vomiting, visual impairment, and altered consciousness with hemodynamic instability is not specific for pituitary apoplexy but raises suspicion for the diagnosis (Table 205-5). Often, this dramatic presentation is the first time the patient is aware of a potential pituitary tumor. As the hemorrhagic infarction resolves, the patient often is left with hypopituitarism.

DIAGNOSIS

Prompt recognition of patients presenting with the triad of headache, vomiting, and visual disturbances is required to prevent death or irreversible neurologic impairment. Clinical evaluation of the patient should begin with a thorough history from the patient, if sufficiently conscious to give one, or from family members. A history of a pituitary tumor should raise the suspicion of apoplexy. More subtle abnormalities associated with pituitary dysfunction (hypofunctioning of thyroid, adrenal, or gonadal systems) may be helpful.

The cornerstone for diagnosis is urgent MRI T2-weighted images. A CT scan can be useful when an MRI is not available or possible.

Urgent measurement of blood chemistries, including electrolytes, kidney function, liver function, complete blood count with platelets, and prothrombin time, can be useful. Because more than 80% of patients will have endocrine dysfunction, urgent measurement of free T_4, TSH, prolactin, and random cortisol can be helpful. Less rapidly available and helpful (and less important in the initial diagnosis and management) are other pituitary hormones such as LH, FSH, estradiol or testosterone, growth hormone, and IGF-I.

Examination of cerebrospinal fluid (CSF) is usually not diagnostic and is unnecessary if the diagnosis of apoplexy is certain. However, if there is bleeding into the CSF as a result of the apoplexy, red blood cells as well as an elevated protein level and xanthochromia can be seen.

TABLE 205-5 SIGNS AND SYMPTOMS OF PITUITARY APOPLEXY

SYMPTOM	APPROXIMATE INCIDENCE
Headache	95%
Vomiting	70%
Vision Defects:	
Visual field defect	65%
Decreased visual acuity	50%
Diplopia (CN III, IV, V, and VI)	40-100%
Hemiplegia	Rare
Meningismus	Rare
Hypotension (cardiovascular collapse)	95%

CN = cranial nerves.

The differential diagnosis of pituitary apoplexy should include other conditions that result in the symptoms of headache, vomiting, visual disturbances, and hemodynamic instability such as infection (meningitis [Chapter 381]), cavernous sinus thrombosis (Chapter 376), migraine (Chapter 367), Rathke cyst hemorrhage (Chapter 377), and hyperemesis gravidarum (Chapter 221). Each of these conditions is itself a medical emergency that requires specific treatment.

TREATMENT

The initial management is stabilization of the hemodynamic status with intravenous 0.9% NaCl boluses to maintain normal tissue perfusion, usually accompanied by high-dose parenteral glucocorticoids (100 mg hydrocortisone every 8 hours intravenously). Emergent surgical decompression may be required in patients who have progressive visual or neurologic impairment.

Although 80% of patients have residual hypopituitarism following apoplexy (with or without surgical decompression), some patients do not display immediate evidence of hypopituitarism. A month after discharge from the hospital and recovery from the acute event, patients should have repeat endocrine testing to determine if the endocrine defect persists. Repeat testing will confirm whether the patient needs to remain on lifelong hormone replacement therapy.

Recurrent apoplexy can occur. MRI of the pituitary should be obtained at 3- to 6-month intervals until the anatomy is stable and then yearly for 5 years.

EMPTY SELLA

Empty sella is a radiologic diagnosis that refers to the observation on imaging of the presence of CSF in the sella turcica accompanied by a flattened pituitary gland (Fig. 205-4). An empty sella is usually noted as an incidental finding when an MRI or CT scan of the skull is performed because of problems unrelated to the pituitary. It can be primary or acquired when a defect in the diaphragma sella allows the arachnoid membrane to herniate into the sella.[10] Patients with acquired empty sella may have a prior history of an infarcted pituitary, surgery, or radiation. If the herniation has been present for years, the sella enlarges, probably owing to persistent exposure to intracranial pressure. Primary empty sella is more frequent in women and may be accompanied by benign intracranial hypertension (Chapters 175 and 367).

In asymptomatic patients, there is no need to measure hormone levels unless there is suspicion of a clinical abnormality related to the pituitary. Pituitary function is usually normal, but about 10% of patients also have mild hyperprolactinemia, probably owing to stretching of the pituitary stalk. Because pituitary function is usually normal, no specific treatment is required. However, if there is concern about possible hypopituitarism, investigation as outlined earlier for hypopituitarism (see Table 205-2) should be undertaken.

PITUITARY TUMORS

EPIDEMIOLOGY AND PATHOBIOLOGY

Pituitary adenomas have an incidence of about 4 to 7 cases per 100,000 and a prevalence of about 1/1000 population.[11] Clonal proliferation of any of the different cell types in the pituitary result in the formation of tumors. Pituitary

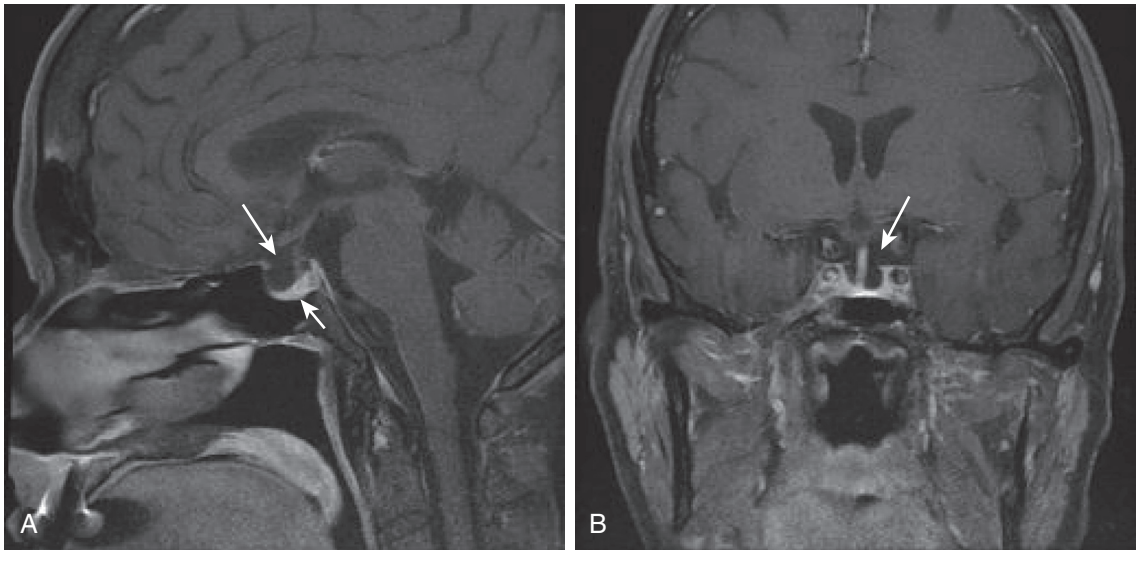

FIGURE 205-4. **Magnetic resonance image of an empty sella. A,** Sagittal postcontrast. Note the void in the sella (*large arrow*) with compression of the normal pituitary against the sella turcica (*small, thin arrow*). **B,** Coronal postcontrast. Sella filled with cerebrospinal fluid and appears as empty.

tumors are classified clinically as functioning if they produce one or more hormones in excess or nonfunctioning if they do not produce excess hormone in blood.[12] Because most functional tumors do not have appropriate physiologic feedback owing to their oncologic nature, they usually cause the clinical syndrome of the excess hormone. However, some functional tumors do not result in excess blood levels of the hormone, owing to a defect in intracellular processing or release.

Prolactinomas, which may account for up to 50% of pituitary tumors, are likely caused when proliferation of the lactotroph results in excess prolactin, with subsequent galactorrhea and hypogonadism. Somatotrophs producing growth hormone, corticotrophs making ACTH, and gonadotrophs making LH and FSH together account for 10 to 20% of adenomas. Nonfunctioning tumors, which mainly cause a mass effect or hypopituitarism, account for 10 to 25%. In addition to functioning and nonfunctioning, tumors are classified by their anatomy based on imaging studies. Microadenomas are less than 10 mm in diameter, whereas macroadenomas are greater than 10 mm in diameter (and typically with extrasellar extension).

Pituitary adenomas are monoclonal and can be locally invasive, but they are rarely malignant. The somatic mutations causing most pituitary tumors remain unknown, but at least six types of inherited predispositions to pituitary tumors are recognized (Table 205-6). When macroadenomas are found in children or when there is a family history of pituitary adenomas, genetic testing is warranted so that appropriate monitoring can occur before the patient is symptomatic. Local expansion of the tumor can cause headaches. The mass effect of the tumor is also responsible for the temporal visual field defects associated with macroadenomas that expand into the suprasellar region and abut against the optic chiasm.

CLINICAL MANIFESTATIONS

The clinical manifestations of pituitary tumors depend in large part on whether they are functional and whether their size compromises the normal function of the pituitary gland and thereby results in clinical symptoms of hypopituitarism.[13] In general, the diagnosis of a tumor due to excess or diminishing hormone secretion presents the greater clinical challenge.

The size of the tumor usually is proportional to the amount of hormone it produces when functioning. Certain tumors are usually diagnosed sooner and therefore are usually smaller on diagnosis than others. For example, gonadotropinomas are usually diagnosed as macroadenomas because their symptoms are usually more subtle than TSH-secreting tumors, in which the symptoms present early so the tumors are usually smaller at the time of diagnosis.

As is true for hypopituitarism of all causes, pituitary tumors have historically been diagnosed more frequently in women of reproductive age because even a slight perturbation in hormonal milieu will disrupt the multiple hormone interactions necessary for a normal menstrual period (Chapter 219). In men or postmenopausal women, slight perturbations in hormone levels (either excess or deficiency) are usually not noticed for several years. More recently, the diagnosis of pituitary adenomas is often an incidental finding on an imaging study obtained for unrelated reasons (e.g., a motor vehicle accident, headaches, or a nonpituitary intracerebral mass effect), and a pituitary microadenoma is an incidental finding. These findings are referred to as "incidentalomas" that otherwise would have avoided clinical detection because they are either silent or subclinical. Incidentalomas can be found in up to 10% of some autopsy series, so they are more common than pituitary tumors found during life. Even after careful endocrine evaluation of patients with incidental tumors, hyper- or hyposecretion of pituitary hormones is found in only a small percentage, and such incidental tumors usually do not increase in size over time.[14]

Other than hormonal effects, reasons for suspicion of a pituitary mass are headaches and visual field abnormalities. A reported 33 to 72% of patients with a pituitary lesion have headaches, a percentage that is greater than the 22% of women and 11% of men in the general population who complain of headaches (Chapter 367), but discerning which patients have a headache from the pituitary lesion and which ones have an unrelated cause for the headache is challenging. Headaches due to pituitary lesions are more common in females and in patients with Rathke cleft cysts and apoplexy.

Severely impaired visual fields can be revealed on examination by confrontation testing. The superior and temporal visual fields are most affected.

MRI is the cornerstone of diagnosis for nonfunctioning tumors and key for the evaluation of functioning tumors. If there is any evidence on MRI that the tumor is close to or abuts the chiasm, formal visual field testing should be performed. Specific diagnosis of pituitary adenomas that are actively secreting a hormone is based on basal hormone levels followed by provocative testing (Table 205-7).

TREATMENT

Surgery

The first line of therapy for pituitary tumors that require treatment is surgery (Video 205-1). The major exception is for prolactinomas (even those that are macroadenomas and result in visual field cuts, headaches, and evidence of selected hypopituitarism), for which medical therapy is the first mode of treatment. Indications for surgery include decompression of mass effects, prevention of further tumor expansion, and normalization of hormone levels. The endoscopic transsphenoidal approach is the standard for decompression or extirpation. Subfrontal craniotomy is reserved for tumors requiring extensive extrasellar exploration. Transsphenoidal surgery is effective, with a less than 5% complication rate and 1% mortality rate in experienced centers, but potential sequelae include sinusitis, hemorrhage, CSF leak, hypopituitarism, and optic nerve injury. About 5% of patients develop transient postoperative diabetes insipidus that rarely persists. About 80 to 90% of microadenomas and only 30 to 60% of macroadenomas are completely cured by transsphenoidal hypophysectomy, but most other patients substantially improve in terms of their hormone levels.

Radiation Therapy

Irradiation (typically 45 Gy) can be adjunctive therapy after surgery or used in combination with medical therapy after curative surgery has failed, based on radiographic or endocrine testing, or when surgery is unable to remove the tumor completely. CyberKnife stereotactic radiotherapy can deliver the same total dose in one treatment as would be provided by traditional external beam radiotherapy over 5 weeks. CyberKnife therapy spares critical radiosensitive structures, but the response can take months up to several years. Proton beam therapy may be performed for intrasellar lesions but is not widely available. Irradiation provides complete remission, and it is most useful for nonfunctioning macroadenomas and for patients who have some residual postoperative tumor or visible tumor. Complications are generally dose related and include partial or complete hypopituitarism (50 to 70% of patients), second tumors in the radiation field (about 2% of patients over a 20-year period), cognitive dysfunction, damage to the optic nerve, and stroke. Stereotactic radiotherapy appears to cause similar complication rates of hypopituitarism but less stroke compared with conventional external beam therapy.

Medical Therapy

Medical therapy varies by the type of tumor (see later for details). Medical therapy is the primary treatment for prolactinomas but is a secondary option when surgery is not curative or is contraindicated by other pituitary tumors.

TABLE 205-6 INHERITED SYNDROMES OF PITUITARY ADENOMAS

SYNDROME	PITUITARY TUMOR	MOLECULAR PATHOGENESIS	MODE OF INHERITANCE	OTHER MANIFESTATIONS
McCune Albright	F/NF	*Gsα SU*	Somatic mutation	Ovary, bone, thyroid dysfunction
Multiple endocrine neoplasias*	F (30% PRL)/NF	Menin (*MEN1*) and MEN4 (*CDKN1B*)	AD	Parathyroid and pancreas tumors
Familial isolated pituitary adenoma (FIPA) syndrome*	F/NF	Arylhydrocarbon receptor interacting protein (*AIP*)	AD with variable penetrance	None
Carney complex (with or without PPNAD)	1/3 with Cushing	Type 1A regulatory subunit of protein kinase A (*PRKARIA*)	AD	Atrial myxomas, spotty skin pigmentation, schwannomas
Primary pigmented nodular adrenocortical disease (PPNAD)	Cushing	Succinate dehydrogenase subunit (*SDH*)	AD	Pheochromocytomas, paragangliomas
Early childhood gigantism	GH	*CD40LG, ARHGEF6, RBMX, GPR101*	X-linked	Gigantism

*Tumors are generally more aggressive and occur at a younger age.

AD = autosomal dominant; F = functioning; GH = growth hormone; NF = nonfunctioning; PPNAD = primary pigmented nodular adrenocortical disease; PRL = prolactin.

TABLE 205-7 SELECTED TESTS TO CONFIRM EXCESS PITUITARY FUNCTION

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Basal IGF-I*	Elevated IGF-I levels are consistent with acromegaly when interpreted in the context of age and nutritional status.
	Oral glucose suppression test: after 75-g glucose load, GH is measured at −30, 0, 30, 60, 90, 120 min.	GH should be suppressed to <1 μg/L in normal persons with polyclonal radioimmunoassays; <0.4 μg/L with two-site monoclonal assays. GH may paradoxically increase in acromegaly.
Prolactin	*Basal prolactin levels*	Elevated prolactin (>200 μg/L) is consistent with a prolactinoma. When prolactin levels are between 20 and 200 μg/L, other causes of hyperprolactinemia should be considered.
Adrenocorticotropic hormone (ACTH)	*Measurement of 24-hr urine free cortisol*	Elevated level is suggestive of Cushing syndrome, but it has several other causes as well.
	Midnight salivary cortisol: special tubes with cotton pledgets available to collect saliva at 11 PM to midnight	In normal persons, the midnight salivary cortisol is very low because of the normal diurnal variation. In patients with Cushing syndrome, the salivary cortisol is elevated.
	Overnight dexamethasone suppression test: dexamethasone (1 mg) PO at midnight, followed by 8 AM plasma cortisol	In normal persons, AM cortisol should be suppressed to <5 μg/dL. Normal test excludes Cushing syndrome. Other disorders can cause failure to suppress normally.
	CRH test: ovine CRH (1 μg/kg) is administered IV, and ACTH and cortisol are drawn at −15, 0, 15, 30, 60, 90, and 120 min.	In Cushing disease, there is usually a 50% increase in ACTH and a 20% increase in cortisol. Adrenal adenoma is associated with suppressed ACTH. Ectopic ACTH is associated with high basal ACTH and cortisol levels that are not affected by CRH.
	Petrosal sinus ACTH sampling: the inferior petrosal sinus is catheterized bilaterally, and plasma ACTH is compared with simultaneous peripheral samples. The sampling can be done in conjunction with CRH or vasopressin stimulation.	In Cushing disease, the ratio of ACTH in the petrosal sinus to the periphery is at least 2 basally and at least 3 after CRH. In ectopic ACTH, the ratio of petrosal sinus to peripheral level is <1.5.
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests*	An inappropriate normal or elevated TSH in the setting of increased free thyroid hormone levels is consistent with a TSH-producing tumor or other causes of inappropriate TSH secretion.
	Free α-subunit level	Elevated levels associated with inappropriately elevated TSH are suggestive of a TSH-producing tumor.
Follicle-stimulating hormone (FSH), luteinizing hormone (LH)	*Basal FSH, LH, testosterone*	Increased LH and testosterone levels in males are consistent with LH-secreting tumors. Elevated FSH and low-normal testosterone are suggestive of an FSH-producing tumor if primary gonadal failure is not present. In females, assessment of excess hormone secretion is difficult because of changes during the menstrual cycle and at menopause.

CRH = corticotropin-releasing hormone; IGF = insulin-like growth factor; TRH = thyrotropin-releasing hormone.

PROGNOSIS

In general, the sooner treatment is initiated to decompress the chiasm (with surgery, or in the case of a medically responsive prolactinoma, with appropriate medication), the more likely vision will be restored; however, visual improvement has been noted even after months of visual field impairment. Even after apparent surgical cure, about 10 to 20% of tumors recur within several years, as manifested by oversecretion of their hormones, and recurrence is more likely if the tumor extended into the suprasellar space or fragmented upon removal.

GROWTH HORMONE

PATHOBIOLOGY

Growth hormone is the main regulator of the growth of bone and other tissues. The human growth hormone gene, along with four other related genes, is located at the growth hormone locus on chromosome 17 where, by gene duplication, these genes are interspersed in the same transcriptional orientation. The five genes not only have a high degree of sequence identity but also exist as multiple isoforms based on variable splicing. The variant expressed in the somatotrophs of the pituitary gives rise to two isoforms. Growth can occur in the fetus and early postnatal state independent of growth hormone; but soon after birth, growth hormone controls growth, and its deficiency results in dwarfism.

Growth hormone is a peptide hormone whose receptor is located on the cell surface. Growth hormone promotes the dimerization of two growth hormone receptors and activates JAK2 by phosphorylation of tyrosine residues. The activated JAK2 in turn activates STAT and an entire cascade of signal factors, thereby resulting in nuclear activation.

The metabolic effects of growth hormone are both direct, by interaction with its tissue receptors, as well as mediated by a serum factor secreted by the liver (somatomedin or insulin-like growth factor-I [IGF-I]). IGF-I in turn acts on a variety of tissues to stimulate body growth. IGF-I is also produced in a variety of tissues including smooth muscle, skin, lung, bone, and cartilage. However, in addition to IGF-I production in the various tissues, growth hormone causes hydrolysis of triglycerides in adipose tissue. In skeletal muscle, growth hormone enhances uptake of amino acids and retention of nitrogen, similar to what would be expected in exercising muscle. Growth hormone also stimulates glycogenolysis and gluconeogenesis.

GROWTH HORMONE DEFICIENCY

PATHOBIOLOGY

Growth hormone deficiency in children may be due to hypothalamic defects in the production, release, or sensing of growth-hormone-releasing hormone (GHRH). Deficiency also can be caused by any congenital disorder of pituitary gland development or from central nervous system defects such as tumors (craniopharyngioma, germinoma, ependymoma, pituitary adenoma, meningioma, medulloblastoma, glioma, Rathke cleft cyst, and arachnoid cyst). Postsurgical disruption of the hypothalamic pituitary axis, trauma, radiation, or infiltration also can cause growth hormone deficiency. Isolated growth hormone deficiency, which is the most common form of nonfamilial deficiency, is responsible for most cases of hypopituitarism in children. Growth hormone deficiency also can occur in combination with other pituitary hormone defects, as discussed earlier.

CLINICAL MANIFESTATIONS

In children, growth hormone deficiency is primarily manifested by slow growth. Due to redundancy of other hormones and factors on growth, children usually are not small for gestational age at birth but can manifest hypoglycemia due to the counter-regulatory effect of growth hormone. There is an increase in body fat, which may result in an appearance that the child is younger than the stated age, and hypogonadism or small genitalia may variably be present. Children usually are diagnosed when found to be shorter than their peers—at well-baby visits, when they enter school, or at puberty.

DIAGNOSIS

In children, the diagnosis of isolated growth hormone deficiency is most reliably made by careful growth measurements, a thorough medical history to exclude other causes of growth failure (renal tubular acidosis [Chapter 104], thyroid disease [Chapter 207], Turner syndrome in girls, or other chronic disease), or combined hormone deficiencies. Because growth hormone is secreted

episodically, measurements of serum growth hormone, IGF-I, and insulin-like growth factor binding protein-3 (IGFBP-3) are also helpful to confirm the diagnosis. Growth hormone levels are typically low, but growth hormone levels are high in the Laron dwarfism syndrome, owing to failure of IGF-I stimulation caused by mutations in the growth hormone receptor. Growth hormone secretion declines with aging, and elderly individuals often have mild and apparently asymptomatic reductions in basal growth hormone levels.[15]

Unless a pituitary disorder has already been confirmed, provocative tests are usually necessary to diagnose growth hormone deficiency that is sufficient to warrant replacement therapy[16] (see Table 205-2). Children with the diagnosis of idiopathic growth hormone deficiency should be retested as adults if they were inadequately diagnosed or had a mild form that resolved in adulthood. If an adult is deficient in three pituitary hormones and has an IGF-I level below the lower limit of normal, provocative testing is not required.

TREATMENT

The treatment of isolated growth hormone deficiency in childhood is replacement of growth hormone. Lonapegsomatropin (0.24 mg/kg/week) is recommended over somatropin (20 to 35μg/kg/week subcutaneously, divided into 6 or 7 daily doses).[A1] The average growth is 9 to 10cm in the first year of treatment, and then it begins to slow down to 6 to 7 cm per year for the next 2 years. At the time of puberty, the dose is often increased to 70 μg/kg/day while monitoring serum IGF-I and IGFBP-3 levels to be sure they are not greater than 2 standard deviations above the upper limit of normal. If growth slows, thyroid function should be checked because hypothyroidism develops in some children who are treated with growth hormone.

Treatment of adult-onset growth hormone deficiency is with human recombinant growth hormone at 2.0 to 5.0 μg/day subcutaneously. The goal is to start with low doses and gradually increase the dose to achieve a serum IGF-1 concentration in the mid-normal range for age. In women who are premenopausal or taking oral estrogen replacement, the dose is 3.0μg/day. The dose is usually given in the evening to mimic the diurnal variation in growth hormone secretion in the physiologic state. Assessment of fat and muscle mass, as well as objective assessment of quality of life, can be helpful to monitor treatment. Although generally safe, complications of treatment include fluid retention (resulting in lower extremity edema or carpal tunnel syndrome) and mild glucose intolerance. Contraindications for treatment include known malignancy, intracranial hypertension, and proliferative retinopathy. The duration of treatment is usually long-term. Lonapegsomatropin, which is the long-acting formulation of growth hormone, may also be efficacious in adults,[A2] but currently has not been approved for weekly treatment in adult-onset growth hormone deficiency.

GROWTH HORMONE EXCESS: ACROMEGALY AND GIGANTISM

Acromegaly is a disease of excessive growth and metabolic derangements caused by proliferation of pituitary somatotrophs and excessive secretion of growth hormone. If left untreated, it results in gross acral and facial disfigurement, cardiac disease, cancer, metabolic abnormalities including diabetes, and increased mortality.

EPIDEMIOLOGY AND PATHOBIOLOGY

The incidence of acromegaly is between 0.2 and 1.1 cases per 100,000 population, with a prevalence of between about 8 and 14 cases per 100,000. The median age at diagnosis is in the fifth decade after a diagnostic delay of about 5 years.

The hypothalamic factor, somatotropin release–inhibiting factor, inhibits the release of growth hormone, whereas growth hormone–releasing hormone stimulates both its synthesis and release. Other growth hormone secretagogues, such as ghrelin in the gastrointestinal tract, directly bind to growth hormone–stimulating receptors in the hypothalamus and induce the release of growth hormone. Furthermore, growth hormone's action is mediated by hepatic IGF-I, which inhibits growth hormone synthesis by stimulating somatotropin release–inhibiting factor in the hypothalamus and pituitary. Acromegaly therefore can be due to pituitary adenomas that produce excessive and uncontrolled amounts of growth hormone, to ectopic production of growth hormone by islet cell tumors (Chapter 211) or lymphomas (Chapters 171 and 172), or to ectopic production of growth hormone–releasing hormone in bronchial carcinoid tumors (Chapter 177), small cell cancers of the lung (Chapter 177), medullary thyroid cancers (Chapter 207), or pheochromocytomas (Chapter 209).

The *MEN1* gene, which codes for menin, is associated with defects in histone methylation, syndromic acromegaly, hyperplastic parathyroid glands, and adenomas of the endocrine pancreas and anterior pituitary. Pituitary adenomas develop in 50% of these patients, and 10% of their tumors secrete growth hormone. Activating mutations in the Gs alpha subunit result in ligand-independent Gs activity, thereby causing elevated cAMP levels and growth hormone hypersecretion.

CLINICAL MANIFESTATIONS

When first encountering patients with excess growth hormone, the handshake by a large, enveloping doughy hand and a rough, resonant voice may be the first hints of acromegaly. Symptoms associated with growth hormone hypersecretion are often not recognized for 10 or more years after their often-subtle onset. The classic coarse facial features are usually not immediately apparent but are recognized in retrospect and after looking at past photographs (Fig. 205-5). Because these pituitary tumors are usually diagnosed only years after the onset of symptoms,[17] they are usually macroadenomas by the time of presentation (75%). Headaches are an initial symptom in up to 60% of the patients, and 10% present with the classic temporal hemianopsia. Tall stature may be present depending on when the growth hormone excess began, with younger age of onset correlating with taller stature.

The effects are most apparent in the bones and soft tissue with bony overgrowth. A protruding lower jaw, splayed teeth, malocclusion, mandibular overbite, and macroglossia are frequently noted. Overgrowth of soft tissues of the pharynx may result in sleep apnea (Chapter 374). Enlargement of the nose and facial bones results in frontal bossing. Enlargement of bones and soft tissue likewise account for the changes patients may observe in ring, shoe, or hat size. Soft tissue growth, including multiple skin tags, is often associated with premalignant colonic polyps and colon cancer (Chapter 179). Hyperhidrosis at rest is very common. Neuropathy, such as carpal tunnel syndrome (Chapter 388), can be seen secondary to nerve entrapment. Increased risks of hypertension, diabetes mellitus, and myocardial hypertrophy predispose patients to ischemic heart disease and heart failure.

DIAGNOSIS

Because growth hormone is secreted in a pulsatile manner and at high amplitudes (>50 ng/mL), random measurements are not very useful for diagnosing or excluding acromegaly. A better way to screen for acromegaly is to measure IGF-I levels (which correlate well with daily secretion of growth hormone and with the activity of the disease) after a 2-hr, 75-g oral glucose tolerance test (Table 205-7). In acromegaly, glucose administration will not suppress growth hormone levels to below 1 ng/mL by a polyclonal antibody immunoassay or below 0.4 ng/mL by a chemiluminescent immunoradiometric assay. Co-secretion of prolactin should be measured, since a significant percentage of tumors co-secrete growth hormone and prolactin, and these findings have implications for medical therapy with dopamine agonists.

After the diagnosis of acromegaly is made based on a full endocrine evaluation, an MRI should be obtained to determine the extent of tumor growth. Although 90% of patients have a visible pituitary adenoma on MRI, 10% of the patients have an empty sella. The rare nonpituitary causes of acromegaly include hypothalamic tumors that make excess growth hormone–releasing hormone or nonendocrine tumors that secrete ectopic growth hormone. Occasionally, selective venous sampling over tumor beds identified radiologically can identify sources of secreted IGF-I or similar compounds.

TREATMENT

The goals of therapy, which is best administered as a multidisciplinary approach with experienced neurosurgeons and endocrinologists,[18–20] are to shrink the tumor, normalize growth hormone and IGF-I levels, prevent tumor mass effects, prevent recrudescence, and avoid precipitating hypopituitarism, thereby reducing the long-term morbidity and mortality that result from excess production of growth hormone. Cure usually is defined by the normalization of random blood levels as well as of IGF-I levels after an oral glucose tolerance test. Transsphenoidal surgery can reduce growth hormone levels below 2.5 ng/mL in 80 to 90% of microadenomas. Macroadenomas have tumor cure rates less than 30%, but the growth hormone level usually is substantially reduced. Radiation is not an effective primary treatment because it will not reduce growth hormone levels until 5 to 10 years later and carries a high risk of hypopituitarism and other complications. However, adjunctive radiation therapy, especially stereotactic radiotherapy, may benefit patients whose macroadenomas persist despite transsphenoidal surgery and medical therapy.

Medical therapies are used as adjunctive therapy if surgery does not cure the tumor or as primary therapy when a surgical cure is not possible, such as when the tumor has invaded the cavernous sinus. Intramuscular somatostatin analogues given every 4 weeks almost always reduce growth hormone and IGF-I levels, and they normalize IGF-I levels in about 50 to 60% of cases. Pasireotide LAR (either 40 mg or 60 mg intramuscularly once every 28 days) is superior to

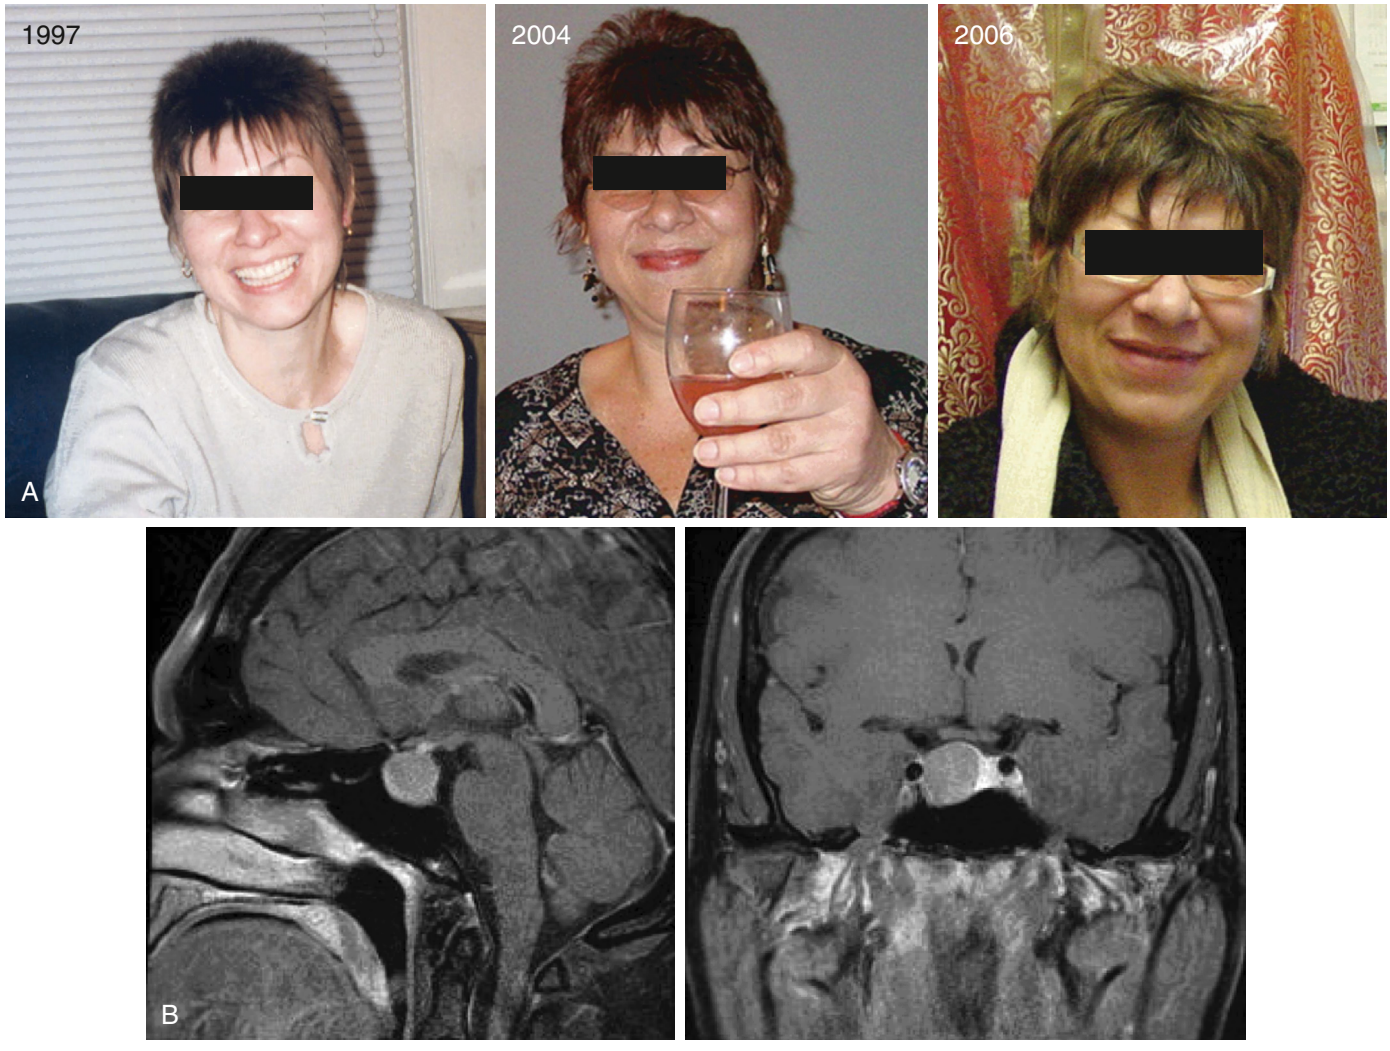

FIGURE 205-5. **Clinical features of acromegaly. A**, Serial photographs of a woman with acromegaly. Over a 9-year period, there is a progressive coarsening of facial features, including enlargement of the nose and lips and development of prognathism. She also experienced hypertension, arthropathy, and enlargement of the hands. **B**, Magnetic resonance image of patient's pituitary adenoma at the time of presentation.

other somatostatin analogues for reducing growth hormone secretion.[A3] Tumor size is reduced modestly in about 50% of cases, and about 10 to 20% of patients who achieve normal levels of growth hormone and IGF-I can eventually be successfully withdrawn from treatment after several years. Side effects of somatostatin analogues include diarrhea and cholelithiasis, although cholecystitis and subsequent cholecystectomy are rare. Oral octreotide (40 mg/day given as 20 mg capsules twice per day 1 hour before meals or 2 hour after meals) is useful in patients who have demonstrated complete or partial biochemical response to injectable octreotide or lanreotide. Oral octreotide should be initiated at the time of the previously scheduled octreotide injection, with the dose up-titrated by 20 mg every 2 to 4 weeks based on the IGF-1 level and clinical symptoms.

Some patients experience additive benefit when other medications are added or combined in low doses to diminish adverse effects. Cabergoline (0.5 to 1 mg 2 times per week), which is a dopamine agonist, often can reduce levels of growth hormone and IGF-I, but levels return to normal in only about 30% of patients when it is used alone. Pegvisomant, which is a biosynthetic analogue of growth hormone, prevents growth hormone from binding to its receptor. When given by daily injection (an initial dose of 40 mg subcutaneously on day 1 followed by 10 to 30 mg daily, with a 5 mg/day adjustment every 4 to 6 weeks based on the goal of normalizing IGF-1 levels), IGF-I levels normalize in greater than 90% of patients,[A4] but it does not affect the size of the tumor itself. It can be reserved for patients who do not respond to other therapies, be used as initial medical therapy for small tumors, or be combined with somatostatin analogues. The most common adverse effect of pegvisomant is an increase in liver enzyme levels.

PROGNOSIS

Treatment can markedly improve symptoms as well as the diabetes and other metabolic derangements,[21] although the arthropathy of acromegaly may progress in about one-third of patients.[22] Patients with larger tumors or higher growth hormone levels are less likely to achieve remission after surgery and more likely to require continued medical treatment.

Patients with acromegaly have a mortality similar to the general population if they achieve growth hormone suppression to less than 1 ng/mL during an oral glucose tolerance test and normal IGF-I levels, especially with ongoing use of somatostatin analogs as adjuvant therapy. However, they have a higher lifetime risk of death due to cancer.

PROLACTIN

Both prolactin and growth hormone have similar amino acid sequences and are present in all vertebrates. During pregnancy, prolactin concentrations increase and, in conjunction with the other hormones of pregnancy, stimulate the breast epithelium to produce milk. Lactotrophs, which are the cells that secrete prolactin, represent 20 to 50% of the anterior pituitary cell population and are the most likely to give rise to pituitary tumors. Prolactin is now implicated not only in lactation but also in inhibition of reproductive function (by suppression of gonadotropins) and support of maternal behavior. A prolactin variant, "big prolactin" or macroprolactin, is a high-molecular-weight variant due to the tendency of prolactin to aggregate and form intermolecular disulfide bridges spontaneously or with IgG. Despite their immunoreactivity, these prolactin variants usually have decreased biologic activity.

Prolactin binds to the prolactin receptor, which is a member of the type 1 cytokine receptor family. Janus kinase-2 mediates prolactin's effect in the target cells. The prolactin receptor is also the receptor for placental lactogens, which are hormones synthesized during pregnancy.

Regulation of prolactin secretion by lactotrophs is primarily under the inhibition of dopamine, which acts through the D_2-type receptors on lactotrophs. Inhibition of the dopamine ("inhibiting the inhibitor") results in a release of prolactin as is seen in nonsecreting pituitary tumors or trauma that disrupts

TABLE 205-8 CAUSES OF HYPERPROLACTINEMIA

DRUG CAUSES	EXAMPLES	MECHANISM	SERUM PRL RANGE PG/ML
Antiemetics	Metoclopramide, domperidone, prochlorperazine	Dopamine receptor blockade	
Antipsychotics	First generation: fluphenazine; haloperidol, others Second generation: paliperidone, risperidone	Dopamine receptor blockade	20-70
Antidepressants, cyclic	Clomipramine	Unknown	20-70
Narcotics	Methadone, morphine, others	Indirect effect of opioid mu receptor activation	20-70
Estrogen	Oral contraceptives	Stimulates PRL at transcription	20-70
NONDRUG CAUSES			
Stress		Hypothalamic	20-70
Pregnancy		Estrogen	20-500
Pituitary adenoma			Macro: 200->10,000 Micro: 20-250
Hypothyroidism		Increase in TRH	Moderate; <100
Chronic renal failure, cirrhosis		Decreased clearance and central effect	Moderate; <100
Chest wall injury, nipple stimulation		Unknown	20-70

PRL = prolactin; TRH = thyrotropin releasing hormone.

the pituitary stalk, thereby preventing dopamine from inhibiting prolactin release. Estrogen is a potent stimulator of lactotroph proliferation and raises the possibility that exogenous estrogen could increase the growth of prolactinomas, although clinical evidence suggests this phenomenon may be true only for macroprolactinomas. Thyrotropin-releasing hormone (TRH) and vasoactive intestinal peptide (VIP) also stimulate the release of prolactin, so when hypothyroidism increases TRH release from the hypothalamus, it causes hyperprolactinemia. In addition to hypothalamic control, prolactin secretion gradually declines at night and rises overnight to reach its highest level in the morning. In addition stress, chest wall stimulation, and pregnancy stimulate the release of prolactin. During pregnancy, high levels of estrogen and progesterone inhibit lactation, and their postpartum decline permits lactation accompanied by the secretion of oxytocin in response to suckling.

PROLACTIN DEFICIENCY

The normal concentration for prolactin is less than 15 to 20 pg/mL in women and less than 10 to 15 pg/mL in men. Low serum levels of prolactin, which can be seen in hyperthyroidism because TRH is suppressed, may prevent adequate lactation in nursing mothers and may be a reliable marker for hypopituitarism when seen with deficiencies in other pituitary hormones. Lactation is not completely absent because nipple stimulation may be sufficient to start milk production. No cases of isolated prolactin deficiency have been reported in men.

HYPERPROLACTINEMIA

EPIDEMIOLOGY AND PATHOBIOLOGY

Hyperprolactinemia occurs in less than 1% of the general population but can be as common as 14% in women with abnormal menses. Among causes of elevated levels of prolactin (Table 205-8) are medications that antagonize dopamine action or increase the activity of endorphins or serotonin. These mechanisms result in mild hyperprolactinemia (<100 pg/mL), but the most common cause of hyperprolactinemia greater than 100 pg/mL is a prolactinoma.

CLINICAL MANIFESTATIONS

Although rare in children (<2 to 3% of intracranial tumors), prolactinomas are usually detected and have clinical symptoms when they become macroadenomas and cause neurologic symptoms (visual problems, headaches), delay puberty, or retard growth. The latter two signs may be due to the direct effects of the tumor on other cell lines or to the effect of excess prolactin on the release of growth hormone and reduced gonadotropin response.

In adult premenopausal females, the typical presentation is galactorrhea and oligomenorrhea. Because galactorrhea is enabled by estrogen, postmenopausal women, who are generally deficient in estrogen, do not develop galactorrhea despite elevated prolactin levels. Prolactin can also suppress GnRH, and therefore LH and FSH, and in turn, estrogen. As a result, symptoms of hyperprolactinemia may also be manifestations of low estrogen levels, such as infertility, decreased libido, and vaginal dryness. Oral contraceptive agents (Chapter 220) can overcome the perturbations in GnRH and induce normal menses even in the presence of elevated prolactin levels. Osteopenia (Chapter 225) may be a direct effect of an elevated prolactin level on the bone as well as its indirect effects on estrogen. If the prolactinoma grows large enough, neurologic symptoms (e.g., vision changes and headaches) can appear even before endocrine manifestations.

In adult men, prolactinomas are usually detected late because a large mass is necessary to cause neurologic or endocrine manifestations. However, excess prolactin inhibits GnRH, thereby lowering testosterone and resulting in decreased libido, impotence, reduced muscle mass, and increased fat mass. In rare situations when men have elevated estrogen levels (e.g., cirrhosis), high prolactin levels can induce gynecomastia and even galactorrhea. In men with osteopenia (Chapter 225), prolactin should be measured because elevated levels decrease testosterone and osteoblasts. Because dopamine inhibits prolactin, nonprolactin–secreting pituitary or hypothalamic tumors that compress the pituitary stalk can also cause an increase in prolactin by disrupting the flow of dopamine to the lactotrophs.

DIAGNOSIS

The diagnosis of hyperprolactinemia[23] is based on a straightforward measurement of elevated blood prolactin by immunoassay. Levels above 100 pg/mL are consistent with an adenoma. When an occasional macroprolactinoma causes a prolactin level higher than 1000 pg/mL, falsely low values may be reported because the high level "overwhelms" the antibody and artificially reduces the measured value. Conversely, prolactin can dimerize with itself ("big prolactin") or complex with circulating IgG ("big big prolactin") to form "macroprolactin" complexes that are not biologically active but may result in elevated prolactin values on some immunoassays.

A brain MRI is recommended in any patient who has a prolactin level >100 ng/mL or is symptomatic (e.g., galactorrhea or amenorrhea) from the elevated prolactin level. In patients who have mildly elevated prolactin levels (<100 pg/mL) but no tumor seen on MRI, the cause may be macroprolactin, a microadenoma too small to be seen on MRI, or "idiopathic" hyperprolactin owing to hypothalamic dysfunction.

Prolactin values slightly above normal but less than 70 pg/mL are usually caused by medications. Other causes include stimulation of the chest wall secondary to chest surgery, pregnancy, lactation, and renal failure as well as prolactin-secreting adenomas.

TREATMENT AND PROGNOSIS

The goals of therapy are to restore normal gonadal function and to shrink the tumor to alleviate any anatomic or neurologic mass effects. The dopamine agonist cabergoline (starting at 0.5 mg orally twice weekly) is effective and relatively well-tolerated (Fig. 205-6). The dose should be titrated to the lowest dose that reduces the serum prolactin level to less than 10 pg/mL. In general, patients with macroprolactinomas require higher doses, usually greater than 2.0 mg/week.

Between 80 and 90% of patients with macroprolactinomas have a greater than 50% decrease in tumor size, and visual field defects can improve within the first week. Patients who cannot tolerate cabergoline due to nausea and dizziness may respond better to bromocriptine (2.5 to 15 mg orally daily), which can be inserted vaginally in women at the same dose. Alternatively, estradiol along with a

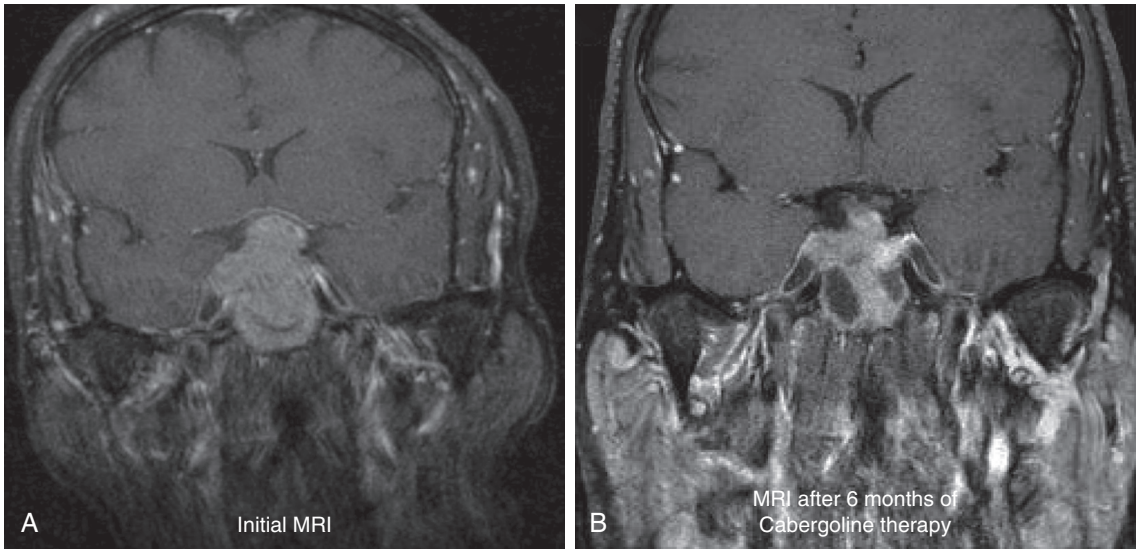

FIGURE 205-6. Magnetic resonance image of a macroprolactinoma before (A) and after (B) commencing cabergoline therapy. A 43-year-old man presented with headaches for 4 weeks and normal vision. Magnetic resonance image (MRI) revealed the large mass. Prolactin on presentation was 8000 ng/dL (normal <20). After 2 doses of cabergoline (0.5 mg orally at night), the serum prolactin level was 2086; after 6 months of treatment, the prolactin level was 15 ng/dL, and repeat MRI showed a significant decrease in the size of the tumor.

progestin (see Table 220-2) can be given in women with microprolactinomas who cannot tolerate dopamine agonists. Because of the concern that these agents could damage heart valves,[24] it is reasonable to perform yearly echocardiograms in patients who have known valvular heart disease or who require long-term therapy at doses greater than 5 mg/week.

Patients who respond well—with suppression of prolactin levels, disappearance of their tumor, and resolution of symptoms for at least a year—should reduce their dose or stop it completely. Prolactin levels and MRI should be repeated at 3 months after stopping the medication, then at 6 months, and then yearly until it is certain there is no recurrence. Macroprolactinomas are more likely to recur than microprolactinomas. If cabergoline is restarted, it should be prescribed at the lowest dose necessary to keep the serum prolactin less than 10 pg/mL.

After a woman is on treatment and her prolactin values normalize, ovulation may be possible. Pregnant patients should discontinue medical therapy. Their prolactin levels should be monitored, acknowledging that pregnancy alone causes prolactin levels to increase. About 25% of macroprolactinomas grow during pregnancy, as evidenced by symptoms of headache and visual field abnormalities, so visual fields should be measured at each trimester. If visual fields are normal, the pregnancy can progress without medication. If visual fields change, discussion should take place about restarting bromocriptine because of more experience with it during pregnancy.

A clear second choice, and usually only in patients in whom pharmacologic intervention is not successful, is transsphenoidal tumor resection. Although cure rates are not as impressive as for medication, prolactin normalizes in 65 to 85% of microadenomas[25] and 30 to 40% of macroadenomas, with recurrent rates of 20% over 10 years. Radiotherapy is rarely used.

ADRENOCORTICOTROPIC HORMONE (ACTH)

INTRODUCTION

ACTH is a 39–amino acid peptide synthesized as part of a precursor polypeptide, proopiomelanocortin (POMC; 241 amino acids). In humans, the *POMC* gene is located at 2p23 on the short arm of chromosome 2 and is composed of three exons. The first exon is the leader sequence and binds the ribosome. The second exon contains the signal sequence, which enables the protein to be translocated to the endoplasmic reticulum and codes for the initial part of POMC. The third exon codes for the mature protein and the polyA tail. In humans, there are three RNA transcripts. The T1 transcript is the form found in the corticotroph cells of the pituitary as well as the hypothalamus. The T2 transcript arises from the 5′ end of exon 3 and is found primarily in peripheral tissues, and the T3 transcript has promoter elements upstream of exon 1 and is expressed in ACTH-secreting tumors, such as small cell lung cancer. POMC undergoes proteolytic cleavage to generate pro-ACTH and β-lipotropin. ACTH is cleaved into corticotropin-like intermediate lobe peptide and α-melanocyte stimulating hormone.

In extrapituitary tumors, the processing of POMC is variable, and a number of intermediates are produced. Therefore, tumors that produce ectopic ACTH usually are accompanied by detectable blood levels of other POMC intermediates that are not seen when a pituitary adenoma causes excess ACTH.

The most important stimulator of ACTH secretion is hypothalamic corticotropin-releasing hormone (CRH). Chronic CRH stimulation causes hyperplasia of corticotroph cells, which rarely can be seen in neuroendocrine tumors that secrete CRH. However, other neurotransmitters and brain peptides (including various cytokines that synergize with hypothalamic hormones, leukemia inhibitor factor, and CRH) also traverse the hypothalamic portal axis and stimulate the corticotroph to release ACTH. In addition, hypoglycemia, stress (as from sepsis, surgery, acute illness), and depression can stimulate the peripheral and hypothalamic cytokines that activate the hypothalamic-pituitary-adrenal axis. Cortisol inhibits the release of ACTH, blunts the response of ACTH to CRH, and inhibits the production of CRH. After prolonged administration of exogenous glucocorticoids and the resulting suppression of the hypothalamic-pituitary-adrenal axis, the recovery of endogenous CRH secretion, which appears to be the rate-limiting step for a return to normal function, can take several months.

ACTH is released in an ultradian pulsatile manner, with 10 to 12 pulses each day, thereby resulting in plasma levels that range from less than 10 to 80 pg/mL. Values are highest around 8 AM and spike with meals. The nadir is usually around 1 to 2 AM. Even the stress of a venipuncture can increase plasma ACTH concentrations. Pulse release combined with a short half-life (minutes) explains why random measurement of ACTH is generally unhelpful except when the random level is very high, as can be seen in primary adrenal insufficiency (low cortisol).

Trauma and infection increase the secretion of CRH, ACTH, and, as a result, cortisol levels. Analogous adjustments in the doses of cortisol replacement therapy are required in seriously ill patients.

ADRENOCORTICOTROPIC HORMONE DEFICIENCY: SECONDARY HYPOCORTISOLISM

EPIDEMIOLOGY AND PATHOBIOLOGY

Secondary adrenal insufficiency refers to states of low cortisolism due to inappropriately low levels of CRH or ACTH. Any congenital or acquired disease that disrupts normal pituitary function can disrupt the formation and release of ACTH.

ACTH deficiency is most often caused when exogenous glucocorticoid treatment suppresses the hypothalamic-pituitary-adrenal axis. Because of the lack of ACTH stimulation, the sudden discontinuation of exogenous glucocorticoids or an unmet increased need for them because of intervening severe stress can cause symptoms and signs of glucocorticoid deficiency.

When ACTH deficiency otherwise occurs in adults, it is almost always accompanied by deficiencies in other pituitary hormones, especially in women who have lymphocytic hypophysitis. Isolated primary ACTH deficiency is

rare,[26] though it can be seen in defects of transcription factors (T-Box19 and pituitary restricted transcription factor), proopiomelanocortin expression, or CRH gene expression.

CLINICAL MANIFESTATIONS

Symptoms of fever, nausea, vomiting, weakness, and fatigue are typically accompanied by relative or absolute hypotension. Abnormal laboratory test findings can include hypoglycemia, hyponatremia, and eosinophilia. Primary adrenal insufficiency (Chapter 208) usually causes more severe cortisol deficiency and associated mineralocorticoid deficiency, whereas secondary adrenal insufficiency is often not as severe and is not accompanied by mineralocorticoid deficiency, because the mineralocorticoids are controlled primarily through the renin-angiotensin system rather than ACTH-dependent mechanisms. As a result, volume depletion is less pronounced in ACTH deficiency, and hyperkalemia is not a part of the clinical syndrome. Another differentiating feature is that MSH levels are low when ACTH levels are low, so hyperpigmentation is not a feature of primary adrenal insufficiency. In women, a reduction in adrenal androgens can reduce libido and lead to loss of hair in the axillary and pubic areas.

DIAGNOSIS

ACTH reserve is usually assessed by the controlled induction of hypoglycemia with intravenous insulin via an insulin tolerance test that directly tests the hypothalamic-pituitary-adrenal axis by stimulating the brain to release cytokines and CRH, which in turn stimulate ACTH release (see Table 205-2). The insulin tolerance test is performed following an overnight fast by administering 0.1 U insulin/kg/body weight intravenously (or 0.05 U if there is high suspicion of ACTH deficiency) using 0.9% NaCl to maintain IV access. The blood glucose level is measured every 15 minutes, monitoring for a glucose level less than 40 mg/dL or when symptoms of hypoglycemia appear (whichever is first). Patients with ACTH deficiency may not rebound from the hypoglycemia and may need to receive 50 mL of 50% dextrose solution to normalize their blood sugar. A normal test would be a cortisol level greater than 18 μg/dL at or soon after confirmed hypoglycemia. The insulin tolerance test should be conducted cautiously in patients with seizure disorders because hypoglycemia may lower the seizure threshold.

Another way to determine ACTH reserve when ACTH deficiency is suspected is to administer CRH (1 μg/kg) intravenously at time "zero," with cortisol measurements at 5, 10, 15, and 30 minutes following the injection. This test, which is not as well standardized as the insulin tolerance test, bypasses the hypothalamus.

TREATMENT

ACTH deficiency responds to glucocorticoid replacement. In general, isolated ACTH deficiency requires only hydrocortisone, usually 20 mg in the morning and 10 mg in the afternoon, to mimic the physiologic profile of cortisol release. Such doses are usually doubled during mild to moderate stress. Emergency hydrocortisone injection kits are worthwhile in case vomiting prevents oral dosing. Stress doses of steroids (e.g., 50 to 75 mg every 8 hours for severe stress) are required for acute illness. Patients who have been taking long-acting, potent glucocorticoids (e.g., prednisone) for months for chronic inflammatory diseases (e.g., asthma [Chapter 75], systemic lupus erythematosus [Chapter 245], or inflammatory bowel disease [Chapter 127]) can be liberated from chronic glucocorticoid treatment if the hypothalamic-pituitary-adrenal axis is stimulated by switching to shorter-acting glucocorticoids (e.g., hydrocortisone) in gradually diminishing doses, oftentimes slowly titrated over many months. However, if the underlying disease for which the steroids were given is still active, other immunosuppressive drugs must be substituted, or the underlying disease will flare.

CUSHING DISEASE

Cushing syndrome reflects excessive tissue exposure to glucocorticoids. The syndrome can be ACTH-dependent or ACTH-independent, but the most common cause is when excess cortisol is produced by the unmitigated release of ACTH from a pituitary adenoma; the term Cushing *disease* is reserved for this specific cause of Cushing *syndrome*. Other causes of ACTH-dependent Cushing syndrome are discussed in Chapter 208.

EPIDEMIOLOGY AND PATHOBIOLOGY

Cushing disease is rare, with an annual incidence of 1.2 to 2.4/million in the population. Approximately 60 to 70% of all cases of Cushing syndrome represent Cushing disease caused by a solitary corticotroph adenoma, although rare cases are caused by corticotroph hyperplasia or, even more rarely, a corticotroph carcinoma. Cushing disease occurs 8 to 10 times more frequently in women than in men. Most tumors are small when they are identified because of the profound biologic effects of excess cortisol, but 10 to 15% present as macroadenomas. Relatively constant high levels of cortisol do not follow the physiologic diurnal variation. The molecular pathology of most corticotroph adenomas is unknown.

CLINICAL MANIFESTATIONS

The symptoms that lead most patients to seek medical care are decreased libido, weight gain, sleep disturbances, emotional lability, and the typical physical changes associated with glucocorticoid excess (see Table 208-1).[27] Most patients experience depression, and some even have suicidal ideation if left untreated. In menstruating females, the first perturbations can be oligomenorrhea and amenorrhea. Patients may also note proximal muscle weakness when entering or exiting an automobile or even brushing their hair. Occasional patients complain of headaches and vision loss depending on the size of the pituitary adenoma. Women can also present with hirsutism and worsening acne. Because of their immunocompromised state, the initial presentation also can be with life-threatening infections and sepsis. The associated hypercoagulable state can result in deep venous thrombosis or pulmonary embolism (Chapter 68).

Common findings on physical examination include central obesity, owing to muscle wasting. Hypertension, which is common, is caused by the direct ability of ACTH to stimulate the secretion of mineralocorticoids as well as glucocorticoids. Large, wide, violaceous striae ("stretch marks") are also seen on the abdomen, under the breasts, in the axillae, and in the upper inner thighs. Compared with the stretch marks in pregnancy, Cushing striae are usually wider than a fingerbreadth, purple in color, and can have subcutaneous bleeding that contributes to their pigmentation. Abnormal adipose tissue is usually seen between the scapulae ("buffalo hump") or in the supraclavicular space. In the face, fat deposition causes "moon facies," and the increased hematocrit contributes to facial plethora (ruddy cheeks) (Table 205-9). Hair growth is increased in an androgen-dependent distribution, and male-pattern baldness develops in women (Fig. 205-7). Multiple ecchymoses on the trunk and extremities can be seen due to bruising from capillary fragility.

TABLE 205-9 CLINICAL FEATURES OF CUSHING DISEASE

GENERAL
Obesity (centripetal distribution)
"Moon facies" and mild proptosis
Increased supraclavicular fat and "buffalo hump"
Hypertension
SKIN
Hyperpigmentation
Facial plethora
Hirsutism
Violaceous striae and thin skin
Capillary fragility and easy bruising
Acne
Edema
Female balding
MUSCULOSKELETAL
Muscle weakness (proximal)
Osteoporosis and back pain
REPRODUCTIVE
Decreased libido
Oligomenorrhea and amenorrhea
NEUROPSYCHIATRIC
Depression
Irritability and emotional lability
Psychosis
Disrupted sleep
METABOLIC
Hypokalemia and alkalosis
Hypercalciuria and renal stones
Glucose intolerance or diabetes mellitus
Impaired wound healing
Impaired resistance to infection
Granulocytosis and lymphopenia
Hypercoagulable state—Pulmonary embolus, deep vein thrombosis
TUMOR MASS EFFECTS
Headache
Visual field loss
Hypopituitarism and mass effect of tumor

FIGURE 205-7. Clinical features of Cushing disease before (A, C) and after (B, D) transsphenoidal resection of an ACTH-secreting pituitary adenoma. An 18-year-old male presented with lower back pain secondary to vertebral fractures, depression, and 20-pound weight gain over a 2-year period. Note the "moon facies" and facial plethora (**A**) and abdominal obesity with thin extremities as well as violaceous striae (**C**). One year after pituitary tumor removal the patient had weight loss, and while the striae remained as scar tissue, they were less violaceous. Muscle mass increased and abdominal obesity decreased. WWW.BOOKBAZ.IR

An additional finding in ACTH-dependent Cushing disease is hyperpigmentation owing to the melanocyte-stimulating hormone (MSH) that is secreted along with ACTH from the adenoma. Although the hyperpigmentation is not as marked as seen in Addison disease (where ACTH levels are usually 10- to 100-fold greater) or as in ectopic hypercortisolism, it is certainly more than seen in ACTH-independent causes of Cushing syndrome.

Patients can have mild glucose intolerance or flagrant diabetes depending on the absolute elevation of the cortisol level as well as its chronicity. The mineralocorticoid excess also commonly leads to kaliuresis and hypokalemia.

DIAGNOSIS

Most patients with obesity, hypertension, and glucose intolerance or diabetes do not have Cushing syndrome, but the presence of the classic physical findings may suggest the need for further investigation. No single diagnostic test can confirm Cushing disease, but a constellation of test results is usually determinative.[28] The first and often most difficult step is to document hypercortisolism. The second step is to determine whether it is caused by elevated ACTH, and if so, the third step is to identify whether the ACTH is coming from the pituitary or an ectopic source (Fig. 205-8).

Blood Tests

Testing usually begins with blood tests of ACTH and cortisol. A morning cortisol level can confirm hypercortisolism, but a random serum cortisol level is unreliable, because of the episodic secretion of cortisol and because 90% of circulating cortisol is bound to cortisol-binding globulin or to albumin. ACTH values above 15 pg/mL are consistent with an ACTH-secreting tumor, either in the pituitary or ectopically. By comparison, very high values (e.g., above 100 pg/mL) are commonly seen in primary adrenal insufficiency. Nearly undetectable plasma ACTH concentrations in the setting of hypercortisolism suggest a primary adrenal source (an adrenal adenoma making cortisol or congenital adrenal hyperplasia).

Late-Night Salivary Cortisol Measurement

An alternative to blood tests is late-night (23:00 to 24:00 hour) salivary cortisol testing. Saliva is collected after refraining from drinking, smoking, eating, or use of oral hygiene products for at least 30 minutes prior to collecting saliva onto an absorbent tube, which is then compressed into a collection tube and brought to the laboratory the next morning. Cortisol is measured by liquid chromatography and tandem mass spectroscopy. Cortisol values greater than 0.09 ug/uL indicate hypercortisolemia. This test has a sensitivity of 80 to 90% for diagnosing Cushing syndrome, but its specificity is lower (70 to 90%). Nevertheless, its excellent sensitivity makes it a good screening test. Salivary cortisol is a measure of free cortisol in the blood and is not affected by elevated cortisol binding globulin, as in serum cortisol measurements.

24-Hour Urine

A properly collected 24-hour urine specimen showing an elevated urine free cortisol level in an unstressed patient with normal renal function is usually sufficient to diagnose Cushing syndrome. Conversely, a normal result is strong evidence against that diagnosis. However, biologic variation and technical challenges hamper the use of this test for the initial screening of Cushing syndrome.

Dexamethasone Suppression Testing

Among the various versions of dexamethasone suppression testing, perhaps the most practical option is a single dose of 1 mg dexamethasone administered at 11 PM, with blood obtained by 8 AM the following morning. A normal response is a serum cortisol concentration of less than 1.8 µg/dL. An alternative cut point, less than 5 µg/dL, is more specific but less sensitive. If the cortisol level is greater than 10 µg/dL, the likelihood of hypercortisolism is high, but the cause could be an unsuppressed pituitary adenoma, an ectopic source of ACTH, or a primary adrenal tumor (Table 205-10).

Patients with corticotroph-secreting macroadenomas or very active tumors may have urine free cortisol levels greater than 1000 µg/dL after 1 mg of dexamethasone and require higher doses of dexamethasone (up to 8 mg q6h for 2 days) to confirm suppressibility and exclude ectopic ACTH production.

CRH Stimulation Test

The CRH stimulation test is one of the most sensitive (93%) and specific (100%) ways to determine if there is an abnormality in the hypothalamic-pituitary-adrenal axis and for diagnosing the etiology of hypercortisolism in ACTH-dependent Cushing disease. The mean ACTH concentrations at 15 and 30 minutes after administrating CRH (1 ug/kg up to 70 ug IV) should increase by at least 35% above the mean basal value in patients with Cushing disease but not in patients with ectopic ACTH secretion.

MRI

The best next step in the evaluation of patients with documented hypercortisolism (i.e., nonsuppression with low-dose dexamethasone and CRH hyperstimulation) is MRI to confirm the presence of a pituitary mass. Unfortunately, 10% of all normal individuals may have slight MRI abnormalities of their pituitary glands, and many patients with Cushing disease may have tumors that are too small to be seen on MRI. However, subjecting a patient to surgical pituitary exploration in the absence of a demonstrable mass is likely to result in an unsuccessful surgery.

Inferior Petrosal Sinus Sampling

If dexamethasone suppression testing and CRH testing are equivocal, inferior petrosal sinus sampling should be performed to confirm the pituitary as the source of the ACTH. Although this test is less reliable in lateralizing the ACTH source (i.e., left vs. right) than it is in confirming that the ACTH source is central in origin, it can exclude ectopic ACTH production by a tumor. However, it usually cannot distinguish an ectopic CRH-secreting tumor from true Cushing disease.

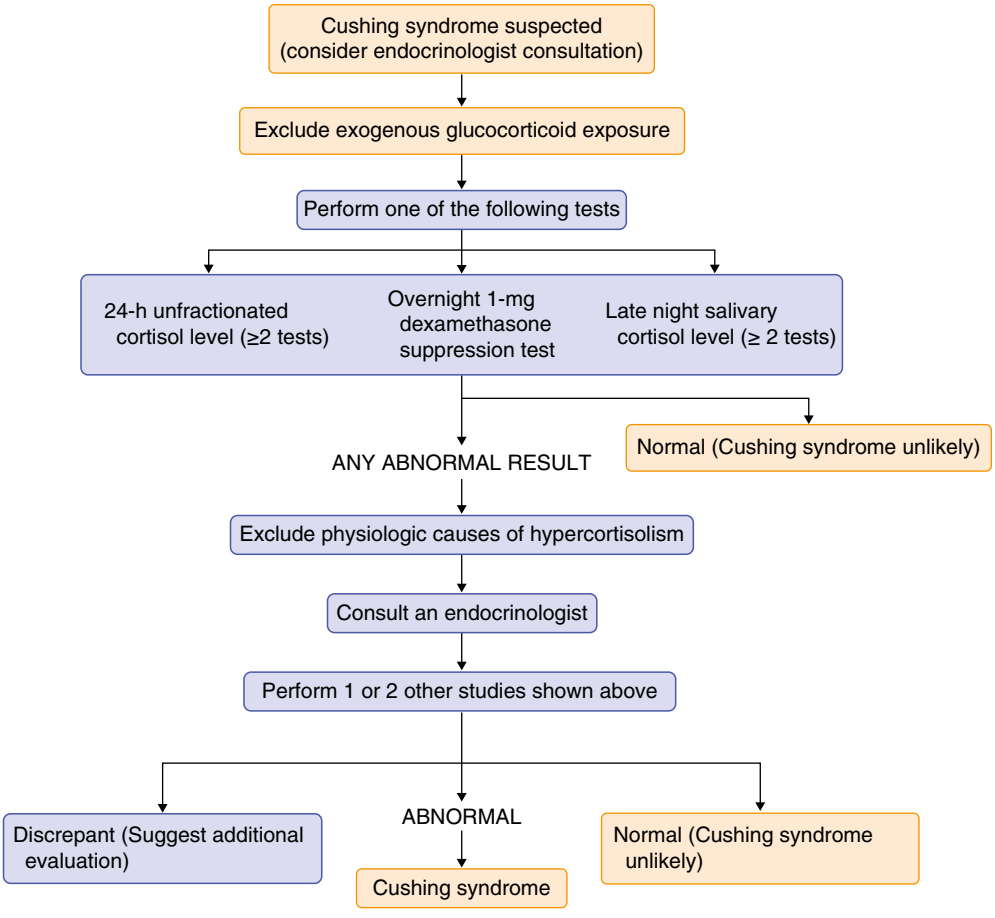

FIGURE 205-8. Approach to testing for suspected Cushing syndrome. Diagnostic criteria that suggest Cushing syndrome are an unfractionated cortisol level greater than the normal range for the assay, a serum cortisol greater than 1.8 μg/dL (50 nmol/liter) after a 1 mg dexamethasone suppression test, and late-night salivary cortisol greater than 145 ng/dL (4 nmol/liter). (Adapted from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab*. 2008;93:1526-1540.)

TABLE 205-10 INTERPRETING RESULTS OF PROVOCATIVE TESTING FOR CUSHING SYNDROME

Cause of hypercortisolism	Plasma ACTH	"Low Dose" oral dexamethasone 0.5 mg q6h for 2 days (measure 24 h urine cortisol)	"High Dose" oral dexamethasone 2.0 mg q6h for 2 days (measure 24 h urine cortisol)	Corticotropin-releasing hormone stimulation test (measure response of ACTH and cortisol at 15 and 30 minutes after injection)
Adrenal adenoma	Undetectable	No suppression	No suppression	No stimulation
Pituitary adenoma	>15 ng/dL	No Suppression	Suppression	Stimulation
Ectopic ACTH-secreting tumor	>100 ng/dL	No suppression	No Suppression	No stimulation
Pseudocushings (obesity, drugs, alcohol)	Normal	Suppression	Suppression	Not indicated

To ensure patient compliance with dexamethasone administration and determine whether there is abnormal metabolism of the dexamethasone, the serum level of dexamethasone can be (but is not usually) measured.
ACTH = adrenocorticotropic hormone.

TREATMENT AND PROGNOSIS

The best chance of curing an ACTH-secreting adenoma is transsphenoidal surgery (Fig. 205-7). Recurrences are seen in 7% of cases when the immediate postoperative plasma cortisol is less than 3 μg/dL compared with 100% when the postoperative plasma cortisol is 3 to 8 μg/dL. In patients with Cushing disease and macroadenomas, only about one third of patients have long-term remission. When initial surgery fails, a second pituitary surgery has a success rate of only about 50%. If postoperative cortisol levels drop below 1 ug/dL, the surgery was likely successful. Although glucocorticoids are not started preoperatively or given postoperatively, the serum cortisol level should be monitored every 4 hours in the first postoperative day. If the cortisol level drops below 5 ug/dL, glucocorticoid replacement should be started. However, several weeks later it should be held in the evening and the following morning to see if the pituitary adrenal axis has recovered. Patients should be closely followed by an endocrinologist with a quarterly urine free cortisol level or late-night salivary cortisol level to assure continued remission.

Pituitary irradiation or bilateral adrenalectomy may be recommended in patients who have a recurrence, in whom surgery is contraindicated (large tumor with invasion of carotid or cavernous sinus), or when a skilled neurosurgeon is not available. Pituitary radiation can take up to 2 to 5 years to be effective, and panhypopituitarism usually results. If a pituitary tumor cannot be demonstrated with certainty, bilateral laparoscopic adrenalectomies will cure the hypercortisolism, but lifetime postoperative steroid replacement is then required.

Medical therapies to inhibit ACTH release from the corticotroph, to block the synthesis of cortisol by the adrenal glands, or to inhibit the action of cortisol at the tissue level are neither particularly well tolerated nor easy to monitor. These therapies are used as last resorts and only by experts. Perhaps the most promising is chemical adrenalectomy with osilodrostat (1 to 30 mg twice daily), which is an inhibitor of 11ß-hydroxylase and can normalize cortisol levels in about 80% of patients,[A5] but with substantial side effects. The glucocorticoid receptor antagonist mifepristone (300 mg once daily, increased in 300 mg increments at 2- to 4-week intervals to a maximum dose of 1.2 grams daily, based on tolerability and control of symptoms) can treat hyperglycemia and can improve quality of life. However, patients may become severely adrenally insufficient because of the receptor blockade, despite very high cortisol and ACTH levels. Other such options (including ketoconazole, mitotane, metapyrone, or etomidate) can be difficult to titrate to normal adrenal function.

NELSON SYNDROME

Nelson syndrome is a rare condition of uncontrolled growth of an ACTH-secreting pituitary adenoma, usually within 3 years after bilateral adrenalectomy has been performed to treat Cushing disease.[29] The incidence of Nelson syndrome following bilateral adrenalectomy can be as high as 43% in patients with macroadenomas, high plasma concentrations of ACTH, and visible pituitary tumors prior to adrenalectomy. Other risk factors for Nelson syndrome

include longer duration of Cushing disease before diagnosis and treatment, younger patients, inadequate glucocorticoid replacement, and tumors with higher mitotic indices.

All patients have high plasma ACTH levels following bilateral adrenalectomy, even those without prior Cushing disease. Such patients should have their hormones measured prior to administration of the AM dose of steroid or 1 hour thereafter. Some experts recommend follow-up MRI every 6 months for several years in patients who have undergone bilateral adrenalectomy after failed transsphenoidal pituitary adenomectomy. Treatment of Nelson syndrome is usually with the same modalities used for ACTH-secreting pituitary adenomas. Despite treatment, some patients have progressive disease.[30]

GONADOTROPINS (FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE)

PATHOBIOLOGY

The three pituitary glycoprotein hormones—FSH, LH, and TSH—have a common α-subunit and a hormone-specific β-subunit that are combined together to form the hormone. Chorionic gonadotropin (hCG), which is structurally very similar to LH, is made in the placenta. These peptides interact with their cognate receptors located in the cell membrane of their target cells. These transmembrane receptors classically have an extracellular domain that binds the hormone, an intramembranous domain, and an intracellular domain that transduces the hormone signal to the cell. Mutations in the extracellular or intracellular domain can cause constitutive activation of the receptor even in the absence of the ligand. The result is the appearance of a hormone-rich state in the absence of the hormone (e.g., precocious puberty due to the constitutive activation of the FSH receptor). Similarly, mutations in the receptor can make it insensitive to the ligand, so that even high hormone levels are not recognized by the receptor. Lastly, due to the similarity of the α-subunit among these glycoprotein hormones, there can be some promiscuity of ligand stimulation when ligand levels are high. During pregnancy, for example, the hCG level is very high and can stimulate the TSH receptor as if TSH were present.

Gonadotropins regulate sexual differentiation, the production of sex steroids, and gametogenesis. In males, FSH receptors are located on Sertoli cells and seminiferous tubules, where they stimulate sperm maturation, whereas LH receptors on Leydig cells in the testis stimulate the production of androgen. Together, FSH and LH induce spermatogenesis (Chapter 216). In females, ovarian FSH receptors on granulosa cells induce the biosynthesis of estrogen, whereas LH receptors on ovarian thecal cells stimulate the synthesis of ovarian androgens and steroid precursors that granulosa cells aromatize into estrogens. The secretion of FSH and LH regulate the menstrual cycle (Chapters 217 and 218).

HYPOGONADOTROPIC HYPOGONADISM

EPIDEMIOLOGY AND PATHOBIOLOGY

Hypogonadotropic hypogonadism or secondary hypogonadism is defined as failure of gonadal function due to pituitary or hypothalamic abnormalities that result in acquired or congenital reductions in LH, FSH, or GnRH.[31] Congenital forms of hypogonadotropic hypogonadism can be due to at least 18 different genes involved in the migration of the GnRH neurons and stimulation of GnRH signaling. Selective deficiency of LH or FSH can rarely be due to inactivating mutations of the β-subunit. Acquired forms can be due to a tumor that interferes with the normal production of LH or FSH, such as Rathke pouch cysts, craniopharyngiomas, or other brain tumors. Functional gonadotropin deficiency can be transient, as seen in chronic illness, starvation, Cushing syndrome, anorexia nervosa (Chapter 200), or alcoholism (Chapter 364). Other causes of acquired hypogonadotropic hypogonadism include infection (tuberculosis [Chapter 299], HIV [Chapter 359], syphilis [Chapter 295]), trauma, infiltrative diseases (e.g., hemochromatosis [Chapter 196] and sarcoidosis [Chapter 83]), as well as medications such as opioids and anabolic steroids.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of hypogonadotropic hypogonadism (Chapter 216) depends on the onset (acquired or congenital), the severity of the defect, and any associated conditions. In congenital forms, patients classically present in the second or third decade of life with poorly or absent sexual characteristics, failure to enter puberty, and primary amenorrhea or infertility. In acquired forms, hypogonadotropic hypogonadism is usually the first manifestation of any process that interferes with normal pituitary function because reductions in FSH and LH usually cause symptoms before reductions in other inhibitory hormones.

The endocrine diagnosis of hypogonadotropic hypogonadism is rather straightforward when men have low levels of testosterone or women have low levels of estradiol in the presence of low or normal levels of gonadotropins. Occasionally, baseline testing is equivocal, so a provocative test is necessary to confirm hypogonadotropic hypogonadism and to distinguish hypothalamic from pituitary disease. In such instances, leuprolide is administered (10 μg/kg subcutaneously), and then LH and FSH are measured at −10, 0, 30, 60, 90, 180, 240, and 1440 minutes later, with estradiol (or testosterone) also measured at baseline and 1440 minutes. In patients with pituitary disease, leuprolide will not stimulate baseline LH or FSH, so levels of testosterone or estradiol will remain flat. In patients with hypothalamic disease, by comparison, the intact pituitary will respond to the leuprolide by increasing levels of LH and FSH and, thereby, levels of testosterone or estradiol.

TREATMENT

Replacement of gonadal hormones is usually the best treatment. In females who have not yet started puberty, estrogen should be initiated at low doses to promote breast development. When breakthrough bleeding occurs about 6 months later, cyclical therapy can be started by adding a progestogen and then increasing estrogen doses gradually over a 2- to 3-year period (Chapter 214). Vitamin D replacement (Chapter 225) should also be provided. Chapter 218 provides guidance for inducing ovulation for women who hope to become pregnant.

In men, transdermal testosterone (50 mg each morning to the surface of the skin, with the dose adjusted monthly to keep the free testosterone in the mid-normal range) is usually preferred because of ease of administration. Alternatively, intramuscular injections at 2- to 4-week intervals (e.g., testosterone cypionate 200 mg every 2 weeks) are effective (see Table 216-6). Doses should be adjusted based on peak and trough testosterone levels (1 week after and just before the next dose) and self-reported libido. Men over age 50 or those that have a family history of prostate cancer or are African American should be screened for prostate cancer before starting treatment. Prostate specific antigen blood levels are expected to increase with therapy, but if the PSA increases more than 1.4 ng/mL in any one year or to >4 ng/mL, a urologic consultation is recommended. If the hematocrit increases to >54%, the hematocrit should be repeated in 2 months, and if still elevated the testosterone should be reduced or discontinued. Several oral preparations of testosterone undecanoate have recently been approved by the FDA.

TUMORS PRODUCING FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE

PATHOBIOLOGY

A majority of pituitary tumors are classified clinically as nonsecreting or nonfunctional adenomas, but the majority (70 to 80%) secrete small amounts of either the α-subunit or β-subunit of LH or FSH (which have no clinical manifestations) or rarely an intact LH or FSH with both α-and β-subunits. FSH is more common than LH, and free α-subunits are more common than β-subunits. Little is known about the molecular basis of these tumors.

CLINICAL MANIFESTATIONS

Most gonadotrophinomas are clinically silent except when their size results in neurologic findings such as visual field problems or headaches. Patients usually present with hypogonadism because secreted gonadotropins are ineffective for stimulating the gonads. Premenopausal females may have ovarian cysts and menstrual disorders. Men commonly are hypogonadal because of low testosterone levels but also develop testicular enlargement from FSH-secreting tumors. In rare tumors that secrete LH, males have elevated testosterone and hemoglobin levels.

DIAGNOSIS

No clinical syndrome is uniquely associated with these tumors. Some patients may have nonspecific moderate elevations of prolactin, but almost all cases are diagnosed postoperatively when the surgical specimen is analyzed.

TREATMENT

Because the major symptoms of the gonadotropin-producing tumors or nonfunctioning adenomas are related to local mass effects and extrasellar extension, the goal of treatment is to reduce the size of the tumor. Transsphenoidal surgery usually can completely or partially reverse any hypopituitarism and visual field impairment but is rarely curative because the tumors are large. Postoperative radiation therapy may benefit patients who have minimal residual tumor. If no tumor is seen on a postoperative MRI, annual monitoring with visual field testing plus CT or MRI is indicated. Tumor markers such as LH and FSH also can monitor tumor activity. For growing tumors, repeat surgery, radiation therapy, or both are indicated. Medical therapy (e.g., dopamine agonists and somatostatin analogues) usually is not helpful.

THYROID-STIMULATING HORMONE

Thyroid function (Chapter 207) and growth are controlled by the action of TSH. Similar to LH and FSH, TSH is composed of a common α-subunit and a β-subunit that is unique to thyrotrophs. Regulation of TSH secretion is by the hypothalamic TRH (Chapter 204) and by thyroid hormone itself. Feedback by thyroid hormone is dependent on intranuclear thyroid hormone receptors, which bind T_3.

T_4 enters the portal-hypophyseal plexus and is deiodinated into T_3 where it then effects pituitary thyrotroph release. TSH acts on thyroid cells via a specific TSH membranous receptor, which contains extracellular, intramembranous, and intracellular domains. Large quantities of hormones similar to TSH, such as hCG, can stimulate the TSH receptor, and thereby the thyroid gland, in the absence of TSH. Furthermore, most thyroid-hormone secreting ("toxic" or "hot") thyroid nodules are due to constitutive activating mutations in the *TSHR* gene.

TSH is secreted in a pulsatile and diurnal variation; but, unlike other pituitary hormones, random measurements of morning serum TSH are consistent enough so that measurement of TSH is clinically useful in determining the extent of thyroid hormone production. Whereas the range of TSH in the normal population is generally between 0.4 and 4.0 mU/L, each person has an individual "thyroid thermostat" set at a specific level. In general, screening for thyroid disease is best done by TSH measurement and, if outside the normal range, confers a high likelihood of thyroid dysfunction (see Chapter 207). Alternatively, when thyroid hormone levels are high and the TSH is not suppressed, secondary hyperthyroidism, of which TSH-secreting pituitary adenomas are in the differential diagnosis (see later), is likely.

CENTRAL HYPOTHYROIDISM

PATHOBIOLOGY

Failure of the pituitary to produce TSH in response to low levels of thyroid hormone is consistent with central or secondary hypothyroidism. An isolated TSH defect is relatively rare and usually related to a genetic factor necessary for thyrotroph differentiation. Pituitary masses that impinge on the thyrotrophs also cause failure to produce sufficient amounts of TSH in the setting of low thyroid hormone levels. However, reduced TSH secretion is usually a late-stage result of pituitary masses, which tend to affect other pituitary hormones first.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical signs and symptoms of central hypothyroidism are indistinguishable from primary thyroid disease, except that the thyroid is nonpalpable. When the thyroid hormone levels are low and the TSH is normal or low, central hypothyroidism is suggested. However, another cause of the constellation of thyroid tests consistent with central hypothyroidism (Table 205-10) is euthyroid sick syndrome (Chapter 207) or nonthyroidal illness, in which cytokines inhibit the release of hypothalamic and pituitary hormones. Euthyroid sick syndrome is also characterized by an increase in serum reverse T_3, which is formed by 5′ deiodination of T_4 and is not biologically active. The same test results are seen in starvation due to activation of the deiodinase. Because isolated TSH deficiency is rare, testing for deficiencies in other pituitary hormones is always recommended.

TREATMENT

Treatment of secondary hypothyroidism is straightforward with a physiologic replacement dose of thyroid hormone (e.g., levothyroxine starting at 1.6 mg/kg and titrated to serum T_4 levels at the upper end of normal if not slightly elevated; see Chapter 207). TSH is not a useful marker of adequate replacement because the thyrotroph is not responsive to the thyroid hormone concentration. In general, titration of thyroxine replacement involves a combination of monitoring the serum T_4 concentration and listening to the patient. The patient should take the thyroxine without food, iron, calcium, or fibrates, all of which can impair its intestinal absorption.

TUMORS THAT SECRETE THYROID-STIMULATING HORMONE

Rarely, pituitary adenomas known as TSHomas or TSH-secreting pituitary adenomas can produce TSH. These tumors account for less than 1% of all cases of hyperthyroidism.

TABLE 205-11 CAUSES OF DISCORDANT THYROID TESTS

LOW TH AND NORMAL OR LOW TSH
Secondary hypothyroidism
Pituitary dysfunction
TRH mutation
TSH mutation
Low TBG or other binding proteins (free T_4 would be normal)
Nonthyroidal illness
Medications
HIGH TH AND NORMAL OR HIGH TSH
TSHoma
Thyroid hormone receptor β resistance to thyroid hormone
Elevated binding proteins (e.g., elevated TBG, familial dysalbuminemic hyperthyroxinemia)
Thyroid hormone habituation
Selenocysteine deficiency syndrome (elevated T_4 due to inability to convert T_4 to T_3)
MCT8-deficiency (elevated T_3 and normal TSH with low T_4)

MCT8 = monocarboxylase transporter 8; T_3 = triiodothyronine; T_4 = thyroxine; TBG = thyroid-binding globulin; TH = thyroid hormone; TRH = thyroid-releasing-hormone; TSH = thyroid-stimulating hormone.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In addition to classic findings of hyperthyroidism, clinical findings in TSHoma include a diffuse goiter, visual field defects, headache, and menstrual irregularities in women. Occasionally, patients do not have hyperthyroid symptoms, most likely due to habituation to the mildly elevated hormone concentrations.

A diagnosis of TSHoma should be considered when patients present with high serum levels of thyroxine and triiodothyronine as well as a normal or elevated TSH level (see Table 205-11). In postmenopausal women, elevated serum levels of the α-subunit of the TSH molecule and nonsuppressed TSH can be seen. Other causes of elevated T_4 and T_3 in the presence of nonsuppressed TSH are shown in Table 205-10.

The diagnosis is rarely straightforward. A combination of tests (e.g., repeat thyroid tests in another laboratory, α-subunit, other pituitary hormones) can confirm the diagnosis, but no single test is diagnostic. In the absence of any history or testing suggestive of a pituitary adenoma, and given the difficulty in distinguishing patients with TSH-secreting tumors from resistance to thyroid hormone, consideration should be given to performing (when available) an analysis for mutations in the thyroid hormone receptor-β gene in patients with elevated free T_4 and T_3, nonsuppressed TSH, and a normal serum α-subunit.

TREATMENT

The goal of treatment is to reduce the size of the tumor with surgery or radiation and to control the hyperthyroidism. In patients with TSH-secreting pituitary tumors, medical or surgical thyroidectomy can cause growth of the tumor. Outcomes are similar to those for gonadotropin-producing adenomas (see earlier).

A β-blocker such as propranolol (80 to 160 mg daily) or atenolol (25 to 50 mg daily) can be given to ameliorate some of the symptoms and signs of hyperthyroidism (Chapter 207). Long-term antithyroid drug therapy or thyroid ablation with radioiodine or surgery is not indicated because sustained reductions in thyroid hormone secretion would be expected to increase TSH secretion and stimulate the tumor's growth. However, if euthyroidism cannot be achieved with somatostatin analogs or dopamine agonists, short-term administration of a thionamide (for example, methimazole 10 mg twice a day; see Chapter 207) is necessary to restore euthyroidism prior to neurosurgery.

NONFUNCTIONING PITUITARY ADENOMAS

Nonfunctioning pituitary adenomas do not cause hormonal excess,[32] although hyperprolactinemia can occur if the pituitary stalk is sufficiently compressed. As a result, these tumors are usually detected when their size causes neurologic symptoms, especially visual field abnormalities, headaches, and ophthalmoplegias. Elevated prolactin levels from stalk compression are much lower than the levels seen with a macroprolactinoma, usually 50 to 100 ng/mL.

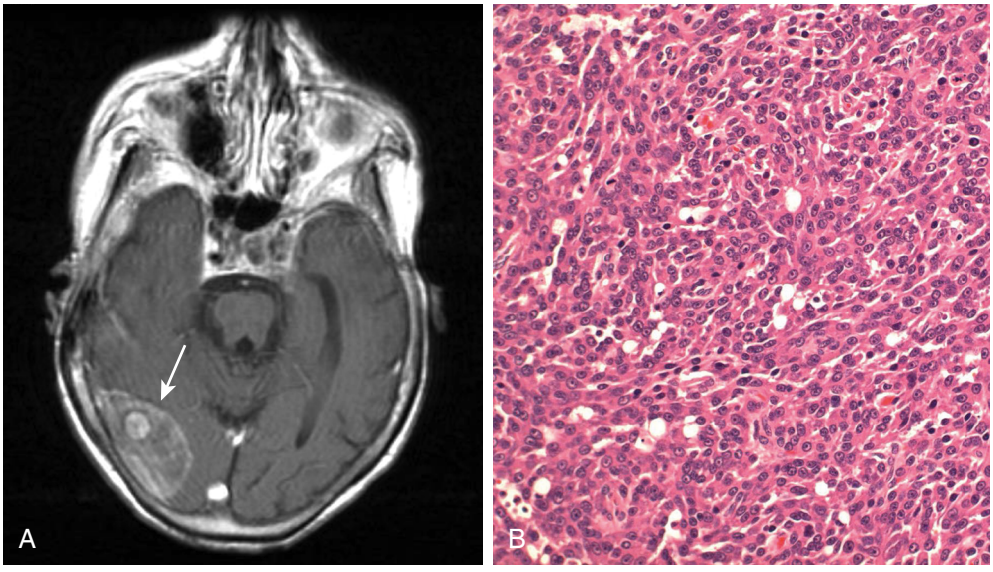

FIGURE 205-9. Pituitary carcinoma. Magnetic resonance image of a cerebral mass in a 43-year-old male patient with an aggressive adenoma that was secreting thyroid-stimulating hormone (**A**). The patient presented with seizures. Biopsy of a brain lesion revealed sheaths of disorganized pituitary cells (**B**).

Oftentimes a nonfunctioning pituitary adenoma is found incidentally when a pituitary mass is discovered in a patient who has a brain imaging study for an unrelated reason. Evaluation (Table 205-7) reveals no hormone excess. Nonfunctioning pituitary adenomas that cause neurologic symptoms require surgical removal, preferably transsphenoidal. Asymptomatic nonfunctioning pituitary adenomas can be monitored by hormonal testing, to assure that no abnormal abnormalities develop, and by MRI, to evaluate the tumor's potential growth. About 50% of tumors grow, and about 20% may require treatment within 7 years.[33]

PITUITARY CARCINOMAS

With few exceptions, pituitary tumors are adenomas that can grow around the sella and invade the carotids and sphenoid sinuses but that do not metastasize. The term *pituitary carcinoma* is restricted to 0.1 to 0.2% of the pituitary tumors that metastasize beyond the immediate vicinity of the sella to the craniospinal region or systemically. Ki-67 is a nuclear protein, and staining tissue for this protein gives the pathologist a marker of the tumor's proliferation index. If the Ki-67 proliferation index is greater than 3%, it suggests a more aggressive pituitary tumor. Approximately half of these tumors produce either ACTH or prolactin, and the remainder are nonsecreting. Surgical debulking, either by a transsphenoidal or open approach depending on its size and the other structures involved by it (e.g., cavernous sinus invasion or attachment to the optic nerve), is the standard therapy, but radiotherapy and temozolomide chemotherapy[34] also have been used because pituitary tumors can have multiple recurrences and be resistant to standard treatments.[35] These aggressive tumors generally have a high mortality rate (over 50%), with a median life expectancy of about 10 months after diagnosis (Fig. 205-9).[36]

206 POSTERIOR PITUITARY

JOSEPH G. VERBALIS

ANATOMY AND HORMONE SYNTHESIS

Vasopressin and oxytocin, which are hormones of the posterior pituitary, are synthesized in specialized neurons of the hypothalmus. These neurons, notable for their large size, are termed *magnocellular neurons*. In the hypothalamus, the magnocellular neurons are clustered in the paired paraventricular and supraoptic nuclei (Fig. 206-1). Vasopressin and oxytocin are also synthesized in parvocellular (i.e., small cell) neurons of the paraventricular nuclei,[1] and vasopressin (but not oxytocin) is also synthesized in the suprachiasmatic nucleus.

Transcription of vasopressin and oxytocin messenger RNA and translation of the vasopressin and oxytocin prohormones occur entirely in the cell bodies of the neurohypophyseal neurons. The prohormones, provasopressin and pro-oxytocin, are packaged along with processing enzymes into neurosecretory granules that are transported out of the perikaryon of the neurohypophyseal neurons via microtubules and down the long axons that form the supraopticohypophysial tract, which terminates in the posterior pituitary. During transport, the processing enzymes cleave provasopressin into vasopressin (9 amino acids), vasopressin-neurophysin (95 amino acids), and vasopressin glycopeptide, or copeptin (39 amino acids). Pro-oxytocin is similarly cleaved to oxytocin (which differs from vasopressin by only two of nine amino acids) and oxytocin-neurophysin. The neurophysins form neurophysin-hormone complexes that stabilize the hormones. Stimulatory (e.g., glutamatergic, cholinergic, and angiotensin) neurotransmitter terminals and inhibitory (e.g., γ-aminobutyric acid and noradrenergic) neurotransmitter terminals control the release of vasopressin through the activity of synaptic contacts on the neurohypophyseal cell bodies. Physiologic release of vasopressin or oxytocin into the general circulation occurs at the level of the posterior pituitary. Although each of the other prohormone fragments are released into the circulation, vasopressin and oxytocin are the only known biologically active components of the prohormones. Factors that stimulate the release of neurohypophyseal hormones also stimulate their synthesis. Because synthesis is delayed, maintenance of a large store of hormone in the posterior pituitary is essential to enable the instantaneous release of each hormone that is necessary following acute hemorrhage (vasopressin) or during parturition (oxytocin). Sufficient vasopressin is stored in the posterior pituitary to support maximal antidiuresis for several days and to maintain baseline levels of antidiuresis for weeks.

With few exceptions, pituitary tumors are adenomas that can grow around the sella and invade the carotids and sphenoid sinuses but that do not metastasize. The term *pituitary carcinoma* is restricted to 0.1 to 0.2% of the pituitary tumors that metastasize beyond the immediate vicinity of the sella to the craniospinal region or systemically. Ki-67 is a nuclear protein, and staining tissue for this protein gives the pathologist a marker of the tumor's proliferation index. If the Ki-67 proliferation index is greater than 3%, it suggests a more aggressive pituitary tumor. Approximately half of these tumors produce either ACTH or prolactin, and the remainder are nonsecreting. Surgical debulking, either by a transsphenoidal or open approach depending on its size and the other structures involved by it (e.g., cavernous sinus invasion or attachment to the optic nerve), is the standard therapy, but radiotherapy and temozolomide chemotherapy[34] also have been used because pituitary tumors can have multiple recurrences and be resistant to standard treatments.[35] These aggressive tumors generally have a high mortality rate (over 50%), with a median life expectancy of about 10 months after diagnosis (Fig. 205-9).[36]

206 POSTERIOR PITUITARY

JOSEPH G. VERBALIS

ANATOMY AND HORMONE SYNTHESIS

Vasopressin and oxytocin, which are hormones of the posterior pituitary, are synthesized in specialized neurons of the hypothalmus. These neurons, notable for their large size, are termed *magnocellular neurons*. In the hypothalamus, the magnocellular neurons are clustered in the paired paraventricular and supraoptic nuclei (Fig. 206-1). Vasopressin and oxytocin are also synthesized in parvocellular (i.e., small cell) neurons of the paraventricular nuclei,[1] and vasopressin (but not oxytocin) is also synthesized in the suprachiasmatic nucleus.

Transcription of vasopressin and oxytocin messenger RNA and translation of the vasopressin and oxytocin prohormones occur entirely in the cell bodies of the neurohypophyseal neurons. The prohormones, provasopressin and pro-oxytocin, are packaged along with processing enzymes into neurosecretory granules that are transported out of the perikaryon of the neurohypophyseal neurons via microtubules and down the long axons that form the supraopticohypophysial tract, which terminates in the posterior pituitary. During transport, the processing enzymes cleave provasopressin into vasopressin (9 amino acids), vasopressin-neurophysin (95 amino acids), and vasopressin glycopeptide, or copeptin (39 amino acids). Pro-oxytocin is similarly cleaved to oxytocin (which differs from vasopressin by only two of nine amino acids) and oxytocin-neurophysin. The neurophysins form neurophysin-hormone complexes that stabilize the hormones. Stimulatory (e.g., glutamatergic, cholinergic, and angiotensin) neurotransmitter terminals and inhibitory (e.g., γ-aminobutyric acid and noradrenergic) neurotransmitter terminals control the release of vasopressin through the activity of synaptic contacts on the neurohypophyseal cell bodies. Physiologic release of vasopressin or oxytocin into the general circulation occurs at the level of the posterior pituitary. Although each of the other prohormone fragments are released into the circulation, vasopressin and oxytocin are the only known biologically active components of the prohormones. Factors that stimulate the release of neurohypophyseal hormones also stimulate their synthesis. Because synthesis is delayed, maintenance of a large store of hormone in the posterior pituitary is essential to enable the instantaneous release of each hormone that is necessary following acute hemorrhage (vasopressin) or during parturition (oxytocin). Sufficient vasopressin is stored in the posterior pituitary to support maximal antidiuresis for several days and to maintain baseline levels of antidiuresis for weeks.

ABSTRACT

Vasopressin and oxytocin, which are the hormones of the posterior pituitary, are synthesized in the hypothalamus and transported to the posterior pituitary, where they are released in response to specific stimuli. The primary physiologic action of vasopressin is its function as a water-retaining hormone. In response to conditions of reduced body water, vasopressin is secreted to maximize urine concentration and reduce urine volume losses. Diabetes insipidus can result from either inadequate vasopressin secretion (central) or inadequate renal response to vasopressin (nephrogenic). Central diabetes insipidus is caused by a variety of acquired or congenital anatomic lesions that disrupt the neurohypophysis. Nephrogenic diabetes insipidus is most commonly congenital, but therapy with drugs such as lithium can cause an acquired form sufficient to warrant treatment. Regardless of the etiology of the diabetes insipidus, the end result is a water diuresis due to an inability to concentrate urine appropriately. Patients develop polyuria and secondary polydipsia from the stimulation of thirst, unless they also have osmoreceptor dysfunction, which impairs thirst. Treatment, which depends on the type of diabetes insipidus, can consist of replacement of vasopressin via synthetic vasopressin analogues in central diabetes insipidus or treatments to reduce polyuria in nephrogenic diabetes insipidus. In all cases, achievement of normal water homeostasis with reduction of polyuria and polydipsia is the goal.

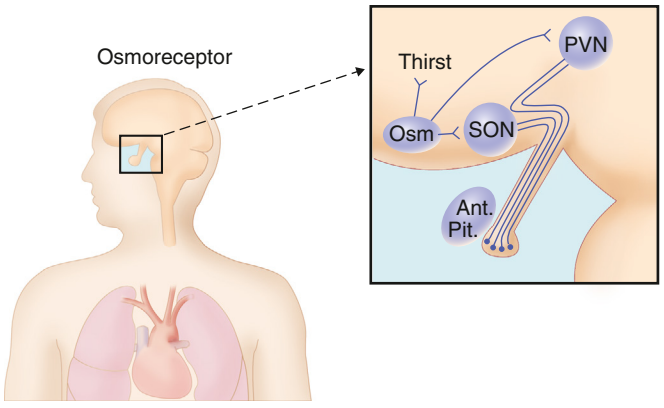

FIGURE 206-1. Sagittal view of the head, demonstrating the position of the neurohypophysis. The magnocellular neurons are clustered in two paraventricular nuclei (PVN) and two supraoptic nuclei (SON). Only one nucleus of each pair is illustrated. The supraoptic nuclei are lateral to the edge of the optic chiasm, whereas the paraventricular nuclei are central along the wall of the third ventricle. The axons of the four nuclei combine to form the supraopticohypophysial tract as they course through the pituitary stalk to their storage terminals in the posterior pituitary. The osmostat (Osm) is in the hypothalamus anterior to the third ventricle; the thirst center (Thirst) is distributed across different brain areas. Ant. Pit. = anterior pituitary. VASOPRESSIN

Vasopressin and Regulation of Osmolality

The primary physiologic action of vasopressin is its function as a water-retaining hormone. The central sensing system (osmostat) for controlling the release of vasopressin is anatomically discrete, located in a small area of the hypothalamus just anterior to the third ventricle (see Fig. 206-1). The osmostat controls the release of vasopressin to allow water retention and also stimulates thirst to cause water repletion.

Osmotic regulation of vasopressin release and osmotic regulation of thirst are usually tightly coupled, but they can be dissociated under pathologic conditions. The primary extracellular osmolyte to which the osmoreceptor responds is sodium. Although basal osmolality in normal individuals ranges between 280 and 295 mOsm/kg H_2O, extracellular fluid osmolality for each individual is maintained within narrow ranges. Increases in plasma osmolality as small as 1 to 2% are sufficient to stimulate vasopressin release. Basal plasma levels of vasopressin are generally 0.5 to 2 pg/mL, a level that maintains urine osmolality above plasma osmolality and urine volume in the range of 1 to 3 L/day. When vasopressin levels are suppressed below 0.5 pg/mL, urine osmolality decreases to below 100 mOsm/kg H_2O, and a free water diuresis (or "aquaresis") ensues at levels that approach 800 to 1000 mL/hour (18 to 24 L/day). Increases in plasma osmolality cause a linear increase in plasma vasopressin and a corresponding linear increase in urine osmolality. At a plasma osmolality of approximately 295 mOsm/kg H_2O, urine osmolality is maximally concentrated to 1000 to 1200 mOsm/kg H_2O. As a result, the entire physiologic range of urine osmolality is accomplished by relatively small changes in plasma vasopressin levels of 0 to 5 pg/mL (E-Fig. 206-1).

Thirst is not stimulated until a somewhat higher plasma osmolality (5 to 10 mOsm/kg H_2O) above the threshold for release of vasopressin. Most humans derive sufficient water from habitual fluid intake and catabolism of food to maintain plasma osmolality below the threshold that activates thirst. Therefore, under normal physiologic conditions, water balance (and hence plasma osmolality) is regulated more by secretion of vasopressin than by thirst. However, with severe degrees of dehydration, thirst is essential to restore body water deficits.

Vasopressin acts on the V_2 subtype of vasopressin receptors in the collecting duct principal cells of the kidney. Vasopressin V_2 receptors activate adenylate cyclase, and the subsequent increased intracellular levels of cyclic adenosine monophosphate (cAMP) initiate the movement of aquaporin-2 (AQP2) water channels to the apical (luminal) membrane of the collecting duct cells. These channels allow facilitated rapid transport of water from the collecting duct lumen into the principal cell along osmotic gradients. The water then exits the cell through the basolateral membrane into the kidney medullary circulation through constitutively expressed aquaporin-3 and aquaporin-4 water channels. This entire process is termed *antidiuresis*.[2] In the absence of vasopressin, the AQP2 channels are reinternalized from the apical membrane into subapical vesicles. This process prevents active reabsorption of water from the collecting duct lumen, thereby resulting in diuresis. In addition to this rapid shuttling of the AQP2 channels to regulate water reabsorption on a minute-to-minute basis, vasopressin acts through the V_2 receptors to regulate long-term stores of AQP2. The absence of vasopressin results in decreased synthesis of AQP2. The hypertonic medullary interstitium is the determinant of the maximal concentration of the urine, which is in equilibrium with the osmolality of the inner medulla of the kidney under conditions of maximal antidiuresis (Chapter 101).

Vasopressin and Pressure and Volume Regulation

High-pressure baroreceptors are located in the aorta and carotid sinus, and low-pressure baroreceptors are located in the right and left atria. Decreases in blood pressure or intravascular volume stimulate the release of vasopressin, whereas situations that increase blood volume or left atrial pressure (e.g., negative-pressure breathing) decrease the secretion of vasopressin.[3] The release of vasopressin in response to changes in volume or pressure is much less sensitive than the release in response to osmoreceptors; generally a 10 to 15% reduction in blood volume or pressure is needed to stimulate the release of vasopressin. However, once arterial pressure falls below this threshold, the stimulated response is exponential, thereby resulting in plasma levels of vasopressin that are markedly greater than those resulting from osmotic stimulation.

The pressor effects of vasopressin are mediated through a separate vasopressin receptor subtype, the V_{1a} receptors, located on vascular smooth muscle. However, the renin-angiotensin-aldosterone system (Chapter 208) is more important for controlling extracellular and blood volume than is the regulation of water homeostasis. Nevertheless, the pressor effects of vasopressin to increase blood pressure can become prominent when other blood pressure regulatory systems are deficient (e.g., autonomic neuropathy [Chapter 386] or blockade of the renin-angiotensin-aldosterone system with medication) or in states of pathologic vasodilation (e.g., liver cirrhosis [Chapter 139], septic shock [Chapter 94]).

Vasopressin and Adrenocorticotropic Hormone

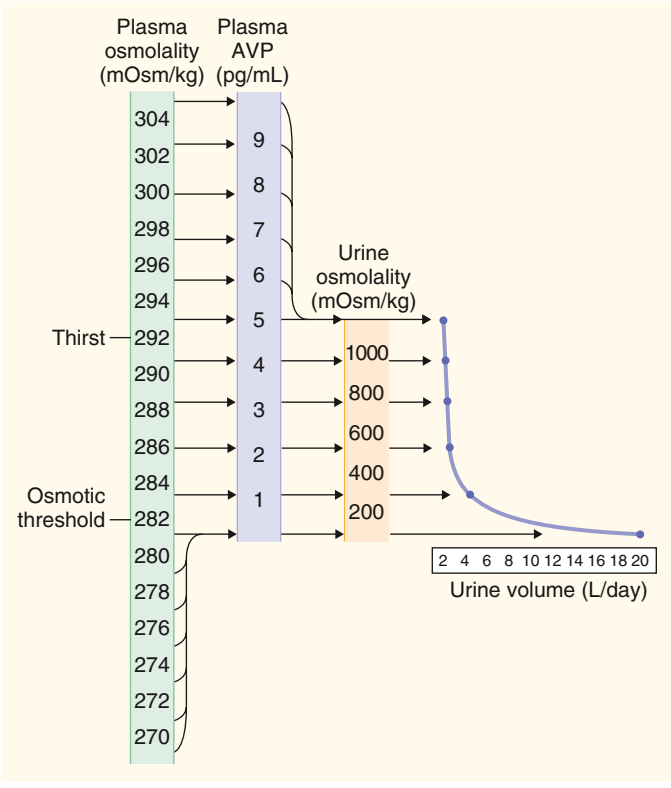
Vasopressin stimulates secretion of adrenocorticotropic hormone (ACTH) via stimulation of the vasopressin V_{1b} receptor subtype that is located on anterior pituitary corticotroph cells. Although the major regulator of ACTH secretion is corticotropin-releasing hormone (Chapter 205), vasopressin activates a different signal transduction system in the corticotrophs, so these hormones have synergistic effects on the secretion of ACTH.

Interaction of Osmotic and Volume Regulation

The vasopressin system optimizes water homeostasis. Water is consumed as available in the absence of stimulated thirst, and vasopressin secretion then regulates water excretion to maintain plasma osmolality. Thirst serves as a reserve mechanism if dehydration becomes excessive. Because pressure-volume regulation of vasopressin is less sensitive, modest changes in pressure or volume, which are exacerbated by upright posture, do not interfere with the regulation of osmolality. Yet the pressor effect of high vasopressin levels serves to maintain blood pressure if volume depletion or hypotension becomes excessive. Usually, the physiologic regulation of osmolality and pressure-volume is synergistic. Dehydration causes an increase in plasma osmolality and a decrease in blood volume, both of which stimulate the release of vasopressin. Conversely, excess fluid administration causes a decrease in plasma osmolality and an expansion of blood volume, both of which inhibit vasopressin secretion.

With volume expansion, the secretion of vasopressin decreases. During pregnancy, plasma osmolality decreases by approximately 10 mOsm/kg H_2O as a result of a resetting of the osmostat for vasopressin secretion, and the osmostat for thirst is reset downward in parallel. These effects appear to be mediated by the placental hormone relaxin.

Abnormalities in water and electrolyte balance are common in the elderly, in part owing to age-related changes in body volume (as much as a 50% decrease in total body water occurs in those older than 75 years) and renal function. The elderly also have a decreased sense of thirst. Despite a normal or even increased ability to secrete vasopressin with age, the ability to achieve either maximal urine concentration to retain water or maximal dilution of urine to excrete water is diminished. Consequently, the elderly are particularly prone to both hypernatremia and hyponatremia (Chapter 102) when faced with diseases or medications that affect water balance.



E-FIGURE 206-1. Idealized schematic of the normal physiologic relationships among plasma osmolality, plasma vasopressin (AVP), urine osmolality, and urine volume. The entire physiologic range of urine osmolality occurs with plasma vasopressin levels from 0 to 5 pg/mL. Increases in plasma osmolality above approximately 290 to 295 mOsm/kg H_2O result in increases in plasma vasopressin but no further concentration of the urine, which is limited by the maximal osmolality in the inner medulla. The relation of volume (calculated on the basis of a constant osmolar load) is inversely exponential to the other parameters. Because of this relationship, urine volume does not change substantially until there is nearly absent vasopressin secretion, after which urine volume increases dramatically. (Calculated from formulas presented in Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. *Kidney Int*. 1976;10:25-37. Figure drawn by J.G. Verbalis, Georgetown University, Washington, DC.)

OXYTOCIN

Prolactin is the main hormone necessary for milk production, but oxytocin is essential for milk secretion. Suckling stimulates tactile receptors in the nipple, thereby producing an afferent signal to the hypothalamus that causes a synchronized release of oxytocin from the posterior pituitary. Oxytocin binds to oxytocin receptors in the breast and induces the alveoli and ductules to eject milk. Upregulation of uterine oxytocin receptors also dramatically increases uterine smooth muscle contractions at the end of pregnancy, when it induces uterine contraction to inhibit blood loss after delivery. No pathologic syndromes of either increased or decreased secretion of oxytocin have yet been defined, although oxytocin is clearly important for maternal and affiliative behaviors. However, because of their structural similarity, at high plasma levels oxytocin can activate vasopressin receptors, and vasopressin can activate oxytocin receptors.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Excess secretion of vasopressin can be caused by abnormally regulated secretion from the posterior pituitary or by ectopic synthesis and secretion of vasopressin by tumors. Osmotically inappropriate secretion of vasopressin causes renal water retention and volume expansion, with consequent dilutional hyponatremia. This disorder, called the syndrome of inappropriate antidiuretic hormone secretion (SIADH), is discussed in Chapter 102.

DIABETES INSIPIDUS

DEFINITION

Diabetes insipidus is the excretion of a large volume of hypotonic insipid (tasteless) urine, usually manifested by polyuria (increased urination) and polydipsia (increased thirst).[4] The large urine volume, usually in excess of 50 to 60 mL/kg/day, must be distinguished from an increased frequency of small urine volumes and from large volumes of isotonic or hypertonic urine, both of which have different clinical significance.

EPIDEMIOLOGY

Diabetes insipidus is a rare disease with a reported prevalence of 1:25,000. Less than 10% of diabetes insipidus can be attributed to hereditary forms such as X-linked nephrogenic diabetes insipidus, which represents 90% of cases of congenital nephrogenic diabetes insipidus and occurs with a frequency of 4 to 8 per 1 million male live births. No sex difference has been reported for the other forms.

PATHOBIOLOGY

Five pathophysiologic mechanisms must be considered in the differential diagnosis of diabetes insipidus.

Central Diabetes Insipidus

Central diabetes insipidus is caused by the inability of the hypothalamus-posterior pituitary to secrete (and usually to synthesize) vasopressin in response to increased osmolality. Central diabetes insipidus can be inherited as an autosomal dominant disease that is typically characterized by an asymptomatic infancy and an onset later in childhood. Most genetic defects are either in the signal peptide of the pre-prohormone or in the neurophysin portion of the prohormone. Most cases are believed to result from disruption of cleavage from the signal peptide or abnormal folding of the neurophysin, which slows trafficking of the mutant prohormone through the endoplasmic reticulum, thereby leading to neuronal cell dysfunction or death.[5] Because this is a cumulative process, this explains the later onset of central diabetes insipidus with these types of mutations.

As few as 10 to 15% of the normal number of vasopressinergic neurons in the hypothalamus is sufficient to maintain an asymptomatic urine volume, but the further loss of just a small number of these neurons produces a rapid increase in urine volume and symptomatic polyuria. The dilute glomerular filtrate is not concentrated in the renal collecting duct, and consequently, a large volume of hypotonic (i.e., dilute) urine is excreted. The result is a secondary increase in serum osmolality, with stimulation of thirst and secondary polydipsia. Levels of vasopressin in plasma are unmeasurable or inappropriately low for the plasma osmolality. Most cases are acquired, for example, from tumors, neurosarcoidosis of the hypothalamus (Chapter 83), tuberculous meningitis (Chapter 299), multiple sclerosis (Chapter 380), histiocytosis (Chapter 155), or brain trauma (Chapter 368), particularly neurosurgical resection of pituitary adenomas,[6] but some are idiopathic, and a small proportion are genetic.

Osmoreceptor Dysfunction

Osmoreceptor dysfunction is a variant of central diabetes insipidus in which the neurohypophysis is intact, but the osmoreceptive cells in the anterior hypothalamus have been damaged (see Fig. 206-1). Because the osmoreceptor cells are necessary for osmotically stimulated vasopressin secretion, the patient manifests polyuria. When such patients are euvolemic, an increase in plasma osmolality produces neither secretion of vasopressin nor a sensation of thirst. When baroreceptors are stimulated by hypovolemia or hypotension, stored vasopressin in the posterior pituitary results in the prompt secretion of vasopressin.

Because the osmoreceptor cells also control thirst, these patients do not have polydipsia. As a result, patients are characterized by elevated serum sodium levels and plasma osmolalities. For this reason, this disorder has also been called essential hypernatremia and adipsic diabetes insipidus, in recognition of the profound thirst deficits found in most of the affected patients.

Lesions that cause osmoreceptor dysfunction are similar to lesions that can cause central diabetes insipidus, but in contrast to central diabetes insipidus, these lesions usually occur more rostrally in the hypothalamus, consistent with the anterior hypothalamic location of the primary osmoreceptor cells. One lesion that is unique to this disorder is an anterior communicating cerebral artery aneurysm (Chapter 377), particularly following clipping or resection of the aneurysm.

Nephrogenic Diabetes Insipidus

Nephrogenic diabetes insipidus is caused when mutations of the vasopressin V_2 receptor or the vasopressin-induced water channel AQP2, or impairments in the signal transduction system linking V_2 receptor activation and AQP2 membrane insertion, make an otherwise normal kidney unable to respond to vasopressin. Familial nephrogenic diabetes insipidus is a rare, X-linked recessive disease, most cases of which (>90%) are due to more than 100 different mutations of the V_2 receptor.[7] In less than 10% of patients, mutations of the AQP2 water channel on chromosome 12 cause autosomal recessive disease. Nephrogenic diabetes insipidus can also be acquired when drugs (such as demeclocycline, which can be used to treat SIADH [Chapter 102], or lithium carbonate, used to treat bipolar disorders [Chapter 362]) or electrolyte abnormalities (such as severe hypokalemia [Chapter 103] and hypercalcemia [Chapter 227]) decrease the synthesis and/or function of AQP2.

As in hypothalamic (central) diabetes insipidus, the dilute glomerular filtrate entering the collecting duct is excreted as a large volume of hypotonic urine. The rise in plasma osmolality stimulates thirst and produces polydipsia. Unlike central diabetes insipidus, however, measured levels of vasopressin in plasma are high or appropriate for plasma osmolality.

Gestational Diabetes Insipidus

Gestational diabetes insipidus is a rare condition produced by elevated levels or activity of placental cysteine aminopeptidase (oxytocinase or vasopressinase) during pregnancy.[8] The rapid destruction of vasopressin produces diabetes insipidus with polyuria and secondary stimulation of thirst with polydipsia. Because of the circulating vasopressinase, plasma vasopressin levels usually cannot be measured.

Primary Polydipsia

Primary polydipsia is a disorder of excess fluid ingestion rather than of vasopressin secretion or activity. Primary polydipsia is sometimes due to a severe mental illness (Chapter 362), such as schizophrenia, mania, or obsessive-compulsive disorder, in which case it is called psychogenic polydipsia. The prevalence in psychiatric hospitals can be as high as 40%, and there is no obvious explanation for the polydipsia. Dipsogenic diabetes insipidus is caused by increased fluid intake that is not due to underlying psychiatric disease. It is usually idiopathic, but it can also be secondary to organic structural lesions in the hypothalamus as for central diabetes insipidus. Primary polydipsia is also sometimes caused by a high fluid intake for valid (e.g., recurrent nephrolithiasis) or unsubstantiated health reasons. These patients lack overt signs of mental illness, but they also deny thirst and usually attribute their polydipsia to habits acquired from years of adherence to a drinking regimen.

Excessive ingested water produces a mild decrease in plasma osmolality, that shuts off the secretion of vasopressin. In the absence of vasopressin action on the kidney, urine does not become concentrated, and a large volume of hypotonic urine is excreted. The amount of vasopressin in plasma is unmeasurable or low but is appropriate for the low plasma osmolality.

Postoperative Diuresis

Sometimes a postoperative water diuresis occurs as a result of water retention during the surgical procedure. During recovery, vasopressin levels fall, and a diuresis of the retained fluid occurs. Persistent polyuria can be mistaken for diabetes insipidus, but if the patient receives intravenous fluids to match urine output, the serum sodium level is almost always normal.

CLINICAL MANIFESTATIONS

Central Diabetes Insipidus

The sudden appearance of hypotonic polyuria after transcranial surgery in the area of the hypothalamus or after head trauma with basal skull fracture and hypothalamic damage strongly suggests the diagnosis of central diabetes insipidus.[9] Central diabetes insipidus occurs commonly in patients with severe brain ischemia and is often indicative of brain death. Transient hyponatremia without preceding or subsequent diabetes insipidus has been reported with surprisingly high frequency after transsphenoidal surgery for pituitary microadenomas, and it is a common cause of hospital readmission after pituitary surgery.[10]

However, even in patients with more insidious progression of a specific disease or in patients with idiopathic central diabetes insipidus, the onset of polyuria is often relatively abrupt and occurs over several days or weeks. Most patients do not notice polyuria until urine volume exceeds 3 to 4 L/day (Fig. 206-2); urine volume does not exceed 4 L/day until the ability to concentrate the urine is severely limited and plasma vasopressin is nearly absent. Urine volume seldom exceeds the amount of dilute fluid delivered to the collecting duct (≈18 to 24 L in humans). Patients often express a preference for cold liquids, which are more effective in assuaging thirst. Both thirst and increased urine output persist through the night, thereby impairing sleep.

Patients with partial central diabetes insipidus have some ability to secrete vasopressin, but this secretion is markedly attenuated at normal levels of plasma osmolality. Therefore, these patients often have urine volume and symptoms similar to those of patients with complete central diabetes insipidus.

Because most patients with central diabetes insipidus have sufficient thirst to drink fluid to match urine output, few laboratory abnormalities are present at the time of initial evaluation. The serum sodium level can be in the high-normal range, whereas the urine sodium level is usually low secondary to the large urine volume. Uric acid is relatively high because of the modest intravascular volume contraction and lack of action of vasopressin on V_{1a} receptors in the kidney, which stimulate the clearance of uric acid. Uric acid levels greater than 5 mg/dL can help to differentiate diabetes insipidus from primary polydipsia. Both myxedema (Chapter 207) and adrenal insufficiency (Chapter 208) impair the ability to excrete free water by renal mechanisms. The simultaneous occurrence of either of these diseases with central diabetes insipidus (as can occur with a tumor of the hypothalamus or pituitary) can decrease an otherwise large urine output, thereby masking the symptoms of diabetes insipidus. Replacement treatment for the anterior pituitary deficiency, especially glucocorticoids, can then cause a sudden and massive excretion of dilute urine. Similarly, the onset of either hypothyroidism or adrenal insufficiency during the course of diabetes insipidus can decrease the need for vasopressin replacement and in some cases can even cause hyponatremia.

Osmoreceptor Dysfunction

Because patients lack thirst, they are chronically dehydrated, often with markedly increased serum sodium levels (hypovolemic hypernatremia). The volume of urine output depends on the degree of dehydration-induced secretion of vasopressin. If sufficient fluid replacement is given to return extracellular fluid volume to normal, these patients are unable to regulate vasopressin by osmolality and again become polyuric, thereby manifesting their underlying central diabetes insipidus.

Nephrogenic Diabetes Insipidus

Symptoms of the X-linked mutations are noted only in affected males, who often present with vomiting, constipation, failure to thrive, fever, and polyuria during the first week of life. Hypernatremia with a hypotonic urine is typically present. Consanguinity and a family history of the disease in both men and women are common in the autosomal recessive form. However, most adult outpatients with nephrogenic diabetes insipidus are not hypernatremic, because the polydipsia produced by a normal thirst response is generally sufficient to maintain water homeostasis. Instead, adults present with polyuria, polydipsia, and a normal sodium level (unlike children, who cannot increase fluid intake and frequently present with severely symptomatic hypernatremia).

Gestational Diabetes Insipidus

In pregnancy, gestational diabetes insipidus causes polyuria, which stimulates thirst and subsequent polydipsia. In general, diabetes insipidus does not persist after the pregnancy ends and does not recur in subsequent normal pregnancies. Polyuria during pregnancy can also manifest in patients who have limited vasopressin reserve (partial central diabetes insipidus) or who respond poorly to vasopressin action (compensated nephrogenic diabetes insipidus).

Primary Polydipsia

Excessive fluid intake also causes hypotonic polyuria and, by definition, polydipsia. This disorder must be differentiated from the various causes of diabetes insipidus. Despite normal pituitary and kidney function, patients share many characteristics of both central diabetes insipidus (vasopressin secretion is suppressed as a result of decreased plasma osmolality) and nephrogenic diabetes insipidus (kidney AQP2 expression is decreased as a result of suppressed plasma vasopressin levels).[11] These patients usually deny true thirst and attribute their polydipsia to bizarre motives, such as a need to cleanse the body of poisons. Primary polydipsia can also be caused by an abnormality in the osmoregulatory control of thirst, in which case it is called dipsogenic diabetes insipidus.[12] These patients have no overt psychiatric illness and invariably attribute their polydipsia to a nearly constant thirst. In primary polydipsia, laboratory studies are generally normal, although the serum sodium concentration is sometimes at the low end of the normal range, and the level of uric acid is generally lower than in patients with other forms of diabetes insipidus.

DIAGNOSIS

Diabetes insipidus should be considered in all patients who present with significant polyuria, defined as urine output greater than 50 mL/kg/day. If the urine volume is lower (or lower than 3 L/day), diabetes insipidus is excluded (Fig 206-2). Although osmotic diuresis secondary to hyperglycemia, intravenous contrast agents, or renal injury is a more common clinical cause of polyuria, the medical history, an isotonic urine osmolality, and routine clinical laboratory tests generally distinguish these disorders from diabetes insipidus.

After polyuria is confirmed, the urine osmolality should be measured.[13] The diagnosis of diabetes insipidus can be made when urine osmolality is inappropriately low in the presence of an elevated plasma osmolality as a result of an increased serum sodium concentration. A urine osmolality <800 mOsm/kg confirms hypotonic polyuria, whereas an osmolality above this value excludes diabetes insipidus. A low serum sodium level and a low plasma osmolality level can then identify primary polydipsia. Otherwise, a plasma copeptin level should be obtained; a very high level (≥21.4 pmol/L) confirms partial or complete nephrogenic diabetes insipidus, a very low level (<2.6 pmol/L) identifies complete central diabetes insipidus, and an intermediate level requires further evaluation with either a water deprivation test or a hypertonic saline infusion test (see Fig. 206-2).

Provocative Testing

The hypertonic saline infusion test measures plasma copeptin levels after 2 hours of infusing hypertonic (3%) NaCl to achieve a serum sodium level of at least 150 mmol/L.[14] However, because some patients may not be acceptable candidates for increasing the serum sodium level to ≥150 mmol/L, another alternative measures copeptin after an arginine infusion, with a level below 3.5 pM at 60 minutes confirming diabetes insipidus.

A water deprivation test should be performed only under controlled observation in the hospital or an appropriately equipped outpatient area.[15] The patient is weighed at the beginning of the test, and all subsequent fluids are withheld. The volume and osmolality of all excreted urine are measured, and the patient is reweighed after each liter of urine output. When two to three consecutive urine samples have an osmolality differing by no more than 10% and the patient has lost at least 2% of body weight, a blood sample is obtained to measure serum osmolality, serum sodium, and plasma vasopressin levels. The patient is then given 2 μg of desmopressin intravenously or subcutaneously and observed for an additional 2 hours. Adults with normal vasopressin secretion concentrate their urine to greater than 800 mOsm/kg H_2O and have less than a 10% increase in urine osmolality in response to the administered desmopressin. Patients with complete central diabetes insipidus have minimal concentration of the urine with dehydration and a marked increase in urine osmolality (usually >50%) in response to administered desmopressin. Patients with nephrogenic diabetes insipidus usually have no increase in urine concentration in response to administered desmopressin. In patients with partial central diabetes insipidus and patients with primary polydipsia, the urine is often somewhat concentrated in response to dehydration but not to the maximum of a normal person. When

Diagnostic testing for diabetes insipidus. [Updated 2019 Feb 10]. In: Feingold KR, Anawalt B, Boyce A, et al., eds. Endotext [Internet]. South Dartmouth: MDText.com, Inc.; 2000. Available from: https://www.ncbi.nlm.nih.gov/books/NBK537591/.)

desmopressin is administered, patients with partial central diabetes insipidus have a further increase (usually >10% but <50%) in urine osmolality, whereas most patients with primary polydipsia have no further increase (i.e., <10%).

In some difficult cases, a decrease in polyuria and thirst with maintenance of normal serum sodium concentration after treatment with a vasopressin agonist can be used to distinguish partial central diabetes insipidus from primary polydipsia. If this approach is used, however, the serum sodium level must be checked within several days to avoid severe hyponatremia in patients with primary polydipsia.

Etiologic Diagnosis

Once the diagnosis of diabetes insipidus has been confirmed physiologically, the next step is to determine its cause.[16,17]

Central Diabetes Insipidus

If testing confirms that inadequate vasopressin secretion is responsible for the polyuria, the underlying cause of central diabetes insipidus must then be determined by magnetic resonance imaging (MRI) of the immediate suprasellar region of the hypothalamus, the pituitary stalk, and the posterior pituitary within the sella turcica.[18] To cause central diabetes insipidus, tumors in the hypothalamic area immediately above the sella must be either sufficiently large to destroy 80 to 90% of the vasopressin cells or be located where the paths of the four nuclear groups converge at the origin of the pituitary stalk, just above the diaphragm sella, and typically thick (i.e., >2 mm) on MRI.

On T1-weighted MRI, the vasopressin and oxytocin stored in neurosecretory granules in the posterior pituitary are visualized as a bright spot in the sella turcica. Most normal subjects have this bright spot (it is absent more

frequently in elderly and dehydrated patients), whereas the bright spot is absent in most patients with central diabetes insipidus. Thickening of the stalk and absence of the bright spot are therefore especially suggestive of a hypothalamic disease process.[19]

Tumors that cause central diabetes insipidus are most often benign primary intracranial tumors such as craniopharyngiomas,[20] ependymomas (suprasellar germinoma), and pinealomas, which arise in the third ventricle. Primary tumors of the anterior pituitary (Chapter 205) cause diabetes insipidus only when substantial suprasellar extension is present. However, rapidly growing intrasellar lesions, such as metastases from carcinomas of the lung, breast, and melanoma or hemorrhage into pituitary adenomas, can cause diabetes insipidus because of insufficient time for the vasopressin axons to adapt by releasing vasopressin from the hypothalamus. Metastases to the hypothalamus can also destroy the supraopticohypophysial tract and produce diabetes insipidus.

Brain trauma (Chapter 368), especially when severe, can also cause diabetes insipidus. In particular, deceleration injuries can cause a shearing of the pituitary stalk at the level of the diaphragm sella. Patients with basilar skull fractures should always be evaluated for possible accompanying diabetes insipidus.

Granulomatous diseases, such as Langerhans cell histiocytosis (Chapter 155), sarcoidosis (Chapter 83), tuberculosis (Chapter 299), and leukemic infiltrates (Chapters 168, 169, and 170) and lymphomas (Chapters 171 and 172) of the hypothalamus (Chapter 204), can cause diabetes insipidus by destroying vasopressin cells.[21] In such patients, the diagnosis is usually suspected on the basis of peripheral manifestations of the respective diseases.

Lymphocytic infundibuloneurohypophysitis is an autoimmune disease, similar to lymphocytic hypophysitis of the anterior pituitary (Chapter 205), in which lymphocytes infiltrate the neurohypophysis to produce diabetes insipidus. The hallmarks of this process are a thickened pituitary stalk and an absence of the pituitary bright spot in a patient with the abrupt onset of polyuria and polydipsia, particularly a postpartum female. When no specific cause is identified, most such cases are probably caused by an autoimmune disease, such as hypophysitis.[22]

A family history suggestive of diabetes insipidus should be investigated with genetic testing for inherited mutations in the vasopressin or vasopressin receptor genes depending on the site of the defect. When no cause is obvious, cerebrospinal fluid may reveal tumor cells or abnormal biomarkers (e.g., elevated angiotensin-converting enzyme levels with neurosarcoidosis, elevated β-HCG levels with germinomas).

Spontaneous (i.e., nontraumatic) diabetes insipidus should not be considered idiopathic until at least 4 years of follow-up. During this interval, annual computed tomography or MRI is indicated to search for a tumor or infiltrative process that may not have been detected at the initial examination.

Nephrogenic Diabetes Insipidus

Other diseases of the kidney can produce polyuria and inability to concentrate the urine secondary to altered renal medullary blood flow or to disorders that inhibit maintenance of the hyperosmolar concentrating gradient in the inner medulla. Renal manifestations of such disorders (e.g., sickle cell disease, sarcoidosis, pyelonephritis, multiple myeloma, analgesic nephropathy) are discussed in Chapter 107.

Primary Polydipsia

All polydipsic patients should be evaluated with MRI of the brain before it is concluded that excessive water intake is due to an idiopathic or psychiatric cause. Primary polydipsia can also be produced by diseases or drugs that cause a dry mouth (Chapter 393) or by any peripheral disorder causing marked elevations of renin or angiotensin II.

TREATMENT

Because excess excretion of water is the primary manifestation of diabetes insipidus, water replacement in adequate quantities avoids the metabolic complications of all forms of this disease. However, oral or intravenous administration of the volume of fluid required to replace the often large urinary losses in diabetes insipidus is difficult and inconvenient. The goal is therapy targeted[23,24] to reduce the amount of polyuria and polydipsia to a tolerable level while avoiding overtreatment, which can produce water retention and hyponatremia.

Central Diabetes Insipidus

The best therapeutic agent for the treatment of central diabetes insipidus is the vasopressin agonist desmopressin, which is available as tablets for oral administration and in either a spray bottle (which delivers a fixed dose of 10 μg in 100 μL) or a bottle with a rhinal catheter (which can deliver 50 to 200 μL [5 to 20 μg]) for intranasal administration. It is generally best to begin therapy with a low dose (e.g., half of a 0.1-mg tablet, 5 μg by the rhinal tube, or a single 100-μL spray of 10 μg) at bedtime and then determine the duration of action by quantifying the polyuria the next day. The duration of action of a single dose varies from 6 to 24 hours; most patients can achieve a good therapeutic response on an every-12-hour schedule for the nasal spray or an 8- or 12-hour schedule for the tablets. The standard therapy for diabetes insipidus in hospitalized adults is parenteral desmopressin (1 to 2 μg every 8 to 12 hours). With any form of administration, serum sodium levels should be monitored regularly to prevent the development of hyponatremia.[25]

With post-traumatic or post-surgical diabetes insipidus, recovery often occurs within the first year of the injury, so allowing the patient to hold a dose of desmopressin once weekly can allow assessment of the need for ongoing therapy. Some patients who have autoimmune neurohypophysitis or granulomatous disease can recover sufficient vasopressin secretion to resolve symptomatic diabetes insipidus after a course of high-dose glucocorticoids under expert guidance (see Chapter 204). Most genetic causes do not recover.

Osmoreceptor Dysfunction

Patients with osmoreceptor dysfunction respond to desmopressin, as do patients with central diabetes insipidus. However, because of their thirst defect, they also must be given a "prescription" for the amount of fluids to be consumed each 24 hours. This prescription must be individualized to each patient, because overconsumption of fluid coupled with desmopressin can produce severe hyponatremia. Daily body weight on an accurate scale can guide hydration, but frequent monitoring of serum sodium levels is usually necessary as well.

Nephrogenic Diabetes Insipidus

Some patients with nephrogenic diabetes insipidus may partially respond to high doses (e.g., 10 to 20 μg) of subcutaneous desmopressin or of intranasal desmopressin (e.g., 100 to 200 μg, which is difficult to administer), but most patients will require additional therapy. Symptomatic nephrogenic diabetes insipidus is usually treated with a thiazide diuretic (e.g., hydrochlorothiazide 12.5 to 25 mg daily),[26] which is enhanced by coadministration of the potassium-sparing diuretic amiloride (5 to 10 mg daily). Some patients benefit from addition of prostaglandin E inhibitors (e.g., indomethacin) that increase cAMP generation by vasopressin and by non–vasopressin-mediated pathways in the kidney. Careful attention should be paid to the possibility that the induced dehydration may increase the concentration of other drugs.

For drug-induced nephrogenic diabetes insipidus, the most direct therapy is discontinuation of the offending agent, if possible. Amiloride (5 to 10 mg daily) can be especially beneficial in cases of nephrogenic diabetes insipidus induced by lithium, because the drug decreases the entrance of lithium into cells in the distal tubule.

Gestational Diabetes Insipidus

Desmopressin, as for central diabetes insipidus, is the drug of choice. During pregnancy, normal serum sodium decreases by approximately 10 mOsm/kg H_2O because of a reset osmostat, so pregnant patients with diabetes insipidus require only enough desmopressin to maintain the plasma osmolality at this lower level. Treatment may be required only during the pregnancy, and the patient often returns to her previous baseline function without the need for therapy when the pregnancy ends. Less commonly, central diabetes insipidus of another cause first becomes symptomatic during pregnancy and then persists afterward, following the usual course of diabetes insipidus.

Primary Polydipsia

For primary polydipsia, treatment commonly focuses on the underlying psychiatric issues (Chapter 362). Preliminary data suggest that the glucagon-like peptide-1 agonist dulaglutide (1.5 mg weekly) can significantly reduce thirst and fluid intake in patients with primary polydipsia[A1] and could therefore be a treatment option for these patients.

Correction of Hyperosmolality

Rarely, severe hypernatremia (Chapter 102) can develop acutely, when patients with diabetes insipidus are unable to drink or are given a hypertonic solution. If the hypernatremia persists for a longer time, the neurons accommodate by producing organic osmolytes (previously called idiogenic osmoles), which limit the amount of brain shrinkage. Once this adaptation has occurred, a too-rapid lowering of osmolality in the extracellular fluid, especially in children, will produce a shift of water into the brain and cause cerebral edema. In this situation in children, desmopressin can be administered to produce constant antidiuresis, and the amount of water given can be regulated to decrease osmolality by no more than approximately 12 mEq/L every 24 hours. By comparison, adults do not require slow correction of hypernatremia.

Postoperatively or after head trauma, diabetes insipidus can be transient (see Prognosis), and the need for long-term antidiuretic maintenance therapy cannot be immediately established.

PROGNOSIS

The prognosis of properly treated diabetes insipidus is excellent. If nephrogenic diabetes insipidus is diagnosed and treated early, kidney damage is only mild to moderate.[27] When central diabetes insipidus is secondary to an invasive disease process, that disease generally determines the ultimate prognosis.

Diabetes insipidus after surgical or traumatic injury to the neurohypophysis can follow any of several well-defined patterns (E-Fig. 206-2). In some patients, polyuria develops 1 to 4 days after injury and resolves spontaneously. Less often, the diabetes insipidus is permanent. Other patients have a triphasic diabetes insipidus, with the first phase of hours or several days of axon shock and lack of function of the damaged neurons, followed by a 2- to 14-day antidiuretic phase that is due to the uncontrolled release of vasopressin from the disconnected and degenerating posterior pituitary or from the remaining severed neurons. Overly aggressive administration of fluids during the second phase does not suppress the uncontrolled vasopressin release from the damaged neurohypophysis and can lead to hyponatremia. This phase is followed by a third phase, in which diabetes insipidus recurs after depletion of vasopressin from the degenerating posterior pituitary gland.

If postoperative diabetes insipidus persists more than several weeks, recovery is less common, and recovery is uncommon after 1 year of continued diabetes insipidus; however, well-documented cases of recovery as long as 10 years after the initiating event have been reported.

Once a deficiency of vasopressin secretion has been present for more than a few weeks, however, it rarely improves, even if the underlying cause of the neurohypophyseal destruction is eliminated. The major exceptions are gestational and postoperative diabetes insipidus, in which spontaneous resolution is the rule.

207 THYROID

ELIZABETH N. PEARCE AND ANTHONY N. HOLLENBERG

OVERVIEW OF THYROID DISEASE

The thyroid gland synthesizes both T_4 and T_3, which are essential for normal human growth and development and for normal physiologic function during adult life. Thyroid hormone levels are genetically set in each individual and are regulated by a negative feedback loop that allows for exquisite control. Disorders of thyroid hormone production, including both hypothyroidism and hyperthyroidism, have diverse causes, are exceedingly common, and present important therapeutic challenges for clinicians who are caring for these patients. Patients who have goiters can be hypothyroid, hyperthyroid, or euthyroid. Thyroid nodules, which have the potential to be malignant, are extremely common in the general population. A systematic approach is critical to discern which nodules must be evaluated further but also to avoid unnecessary therapy, including thyroid surgery.

PATHOBIOLOGY

The thyroid gland is an essential endocrine organ whose principal function is to secrete two thyroid hormones: 3,5,3′,5′–l-tetraiodothyronine (also known as thyroxine or T_4) and 3,5,3′–l-triiodothyronine (also known as T_3) from thyroid follicular cells. The gland itself also contains parafollicular or C cells that produce the hormone calcitonin, which plays little role in normal human physiology but can be used pharmacologically to treat hypercalcemia. T_4 and T_3 are absolutely required for normal development of the human fetus, and lack of thyroid hormones either early in utero or immediately after birth has severe neurologic consequences. After birth, thyroid hormone is critical for normal growth and development through adulthood and is also responsible for the control of many aspects of normal physiologic function, including cardiac contractility and heart rate, free water clearance, and regulation of body weight and energy expenditure.

T_3 is the principal biologic congener of the thyroid hormones, whereas T_4 functions as a pro-hormone that is converted to T_3. The actions of T_3 are mediated by a family of thyroid hormone receptors that exert their actions primarily in the cell nucleus to regulate physiology by changing gene expression.

The thyroid gland develops in the first trimester of pregnancy from the anterior endoderm. Mutations in key transcription factors that are responsible for this development can lead to congenital hypothyroidism, which is found in 1 per 3500 births. Thyroid follicular cells, which are derived from embryonic stem cells, also can be derived from induced pluripotent stem cells.[1] The thyroid gland weighs approximately 10 to 20 grams in adults and is shaped like a butterfly, with a right lobe and left lobe that are each approximately 4 cm in height and 2 cm in width with an isthmus that bridges the two lobes. In a small percentage of patients, a vestigial pyramidal lobe, which extends off either the right or left lobe, is a remnant of the embryonic tract of the gland from the pharynx to its position in the neck. Because of this tract, ectopic thyroid tissue can be located behind the tongue or anywhere in the neck region. Histologically the gland is composed of thyroid follicular cells, which organize themselves into follicular units that surround a colloid center. C cells, which derive through a separate process from pharyngeal ectoderm, are interspersed in between the thyroid follicular units and have a distinct histological appearance.

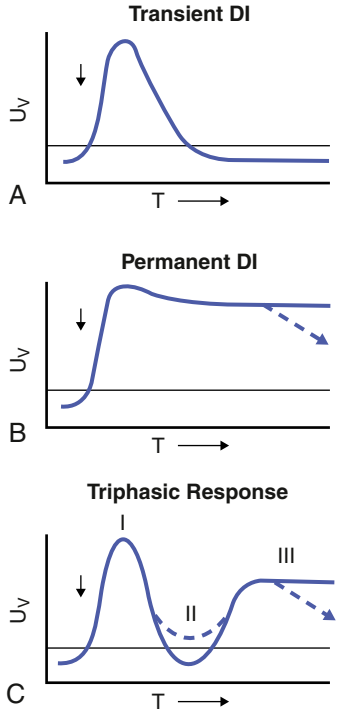
Thyroid Hormone Synthesis and Secretion

Thyroid hormones are the only iodinated proteins in humans, and their synthesis is dependent on the appropriate dietary intake of iodine (approximately 150 ug/day). In many regions of the world, iodine intake is below the threshold, thereby leading to thyroid growth, or goiter, as the gland is stimulated by the pituitary gland to try to compensate for the deficiency of thyroid hormone production. Circulating iodine is actively concentrated in the thyroid follicular cell by the sodium-iodide symporter, which is a 13-member transmembrane protein located at the junction between the circulation and the thyroid follicular cell. After iodine enters the cell, it moves to the apical membrane where it is effluxed into the colloid space by specific transporters. When it is out of the thyroid follicular cell, iodide is oxidized by the enzyme thyroid peroxidase, which requires the production of hydrogen peroxide in the colloid space. The oxidized iodide is then coupled to tyrosyl residues present on the 660-KD protein thyroglobulin. Specific residues on thyroglobulin can either be monodeiodinated or diiodinated, thereby allowing for the formation of T_4 or T_3. When it is back in the thyroid follicular cell, the thyroglobulin backbone is lysosomally digested, and mature thyroid hormones are secreted into the blood stream. The human thyroid secretes T_4 and T_3 in a ratio of 14:1. Genetic defects in any of the key enzymatic processes (e.g., mutations in thyroid peroxidase) can lead to congenital hypothyroidism (E-Fig. 207-1).

Thyroid Hormone Transport and Metabolism

Once secreted, circulating T_4 and T_3 are tightly bound to plasma proteins, especially thyroxine binding globulin. The ratio of T_4 to T_3 in the circulation is 60:1 because T_4 is more tightly bound to thyroxine binding globulin and thus has a longer half-life than T_3 (5 to 7 days compared with about 24 hours). To mediate their genomic effects, thyroid hormones first enter target cells via specific thyroid hormone transporters that are differentially expressed across cells.[2] The most well known of these transporters is the monocarboxylate 8 transporter, which is mutated in Allen-Herndon Dudley syndrome, a rare X-linked neurologic syndrome of devastating consequences caused by the inability of thyroid hormones to cross the blood-brain barrier in utero. In addition to allowing the transport of thyroid hormones into cells, the monocarboxylate 8 transporter is also responsible for allowing T_4 to be secreted by the thyroid follicular cell into the circulation.

After thyroid hormones enter target cells, local T_3 availability is regulated by a family of deiodinases that can either activate T_4 to T_3 or inactivate T_4 to the inert reverse T_3 or inactivate T_3 to T_2. The deiodinase family contains three members. Type 1 deiodinase is highly expressed in the liver, has both activating and inactivating properties, but preferentially converts T_4 to T_3. Type 2 deiodinase, which also is an activating deiodinase, is highly expressed in the pituitary, central nervous system (CNS), and skeletal muscle. In contrast, type 3 deiodinase is an inactivating enzyme that is highly expressed during development in the CNS and in sensory organs (E-Fig. 207-2).



E-FIGURE 206-2. **A to C, Diagrammatic summary of the major patterns of post-operative and post-traumatic diabetes insipidus (DI).** The abscissa represents time (T) after the initial injury (*arrow*); the ordinate represents urinary volume (Uv) relative to a hypothetical "normal" urine output of 2 to 3 L/24 hours (*solid line*). See the discussion in the text. During the triphasic response (C), uncontrolled release of vasopressin from the disconnected or damaged posterior pituitary gland causes an antidiuresis that can lead to water retention and a dilutional hyponatremia. Diabetes insipidus returns as the third phase after the stored hormone in the posterior pituitary has been depleted. (From Verbalis JG, Robinson AG, Moses AM. Postoperative and post-traumatic diabetes insipidus. In: Czernichow AP, Robinson A, eds. *Diabetes Insipidus in Man: Frontiers of Hormone Research*. Basel: S Karger; 1985:247.)

207 THYROID

ELIZABETH N. PEARCE AND ANTHONY N. HOLLENBERG

OVERVIEW OF THYROID DISEASE

The thyroid gland synthesizes both T_4 and T_3, which are essential for normal human growth and development and for normal physiologic function during adult life. Thyroid hormone levels are genetically set in each individual and are regulated by a negative feedback loop that allows for exquisite control. Disorders of thyroid hormone production, including both hypothyroidism and hyperthyroidism, have diverse causes, are exceedingly common, and present important therapeutic challenges for clinicians who are caring for these patients. Patients who have goiters can be hypothyroid, hyperthyroid, or euthyroid. Thyroid nodules, which have the potential to be malignant, are extremely common in the general population. A systematic approach is critical to discern which nodules must be evaluated further but also to avoid unnecessary therapy, including thyroid surgery.

PATHOBIOLOGY

The thyroid gland is an essential endocrine organ whose principal function is to secrete two thyroid hormones: 3,5,3′,5′–l-tetraiodothyronine (also known as thyroxine or T_4) and 3,5,3′–l-triiodothyronine (also known as T_3) from thyroid follicular cells. The gland itself also contains parafollicular or C cells that produce the hormone calcitonin, which plays little role in normal human physiology but can be used pharmacologically to treat hypercalcemia. T_4 and T_3 are absolutely required for normal development of the human fetus, and lack of thyroid hormones either early in utero or immediately after birth has severe neurologic consequences. After birth, thyroid hormone is critical for normal growth and development through adulthood and is also responsible for the control of many aspects of normal physiologic function, including cardiac contractility and heart rate, free water clearance, and regulation of body weight and energy expenditure.

T_3 is the principal biologic congener of the thyroid hormones, whereas T_4 functions as a pro-hormone that is converted to T_3. The actions of T_3 are mediated by a family of thyroid hormone receptors that exert their actions primarily in the cell nucleus to regulate physiology by changing gene expression.

The thyroid gland develops in the first trimester of pregnancy from the anterior endoderm. Mutations in key transcription factors that are responsible for this development can lead to congenital hypothyroidism, which is found in 1 per 3500 births. Thyroid follicular cells, which are derived from embryonic stem cells, also can be derived from induced pluripotent stem cells.[1] The thyroid gland weighs approximately 10 to 20 grams in adults and is shaped like a butterfly, with a right lobe and left lobe that are each approximately 4 cm in height and 2 cm in width with an isthmus that bridges the two lobes. In a small percentage of patients, a vestigial pyramidal lobe, which extends off either the right or left lobe, is a remnant of the embryonic tract of the gland from the pharynx to its position in the neck. Because of this tract, ectopic thyroid tissue can be located behind the tongue or anywhere in the neck region. Histologically the gland is composed of thyroid follicular cells, which organize themselves into follicular units that surround a colloid center. C cells, which derive through a separate process from pharyngeal ectoderm, are interspersed in between the thyroid follicular units and have a distinct histological appearance.

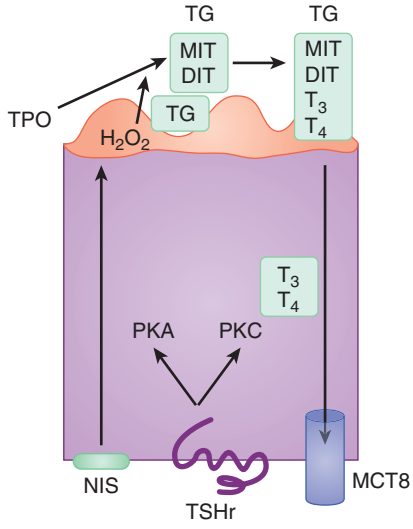
Thyroid Hormone Synthesis and Secretion

Thyroid hormones are the only iodinated proteins in humans, and their synthesis is dependent on the appropriate dietary intake of iodine (approximately 150 ug/day). In many regions of the world, iodine intake is below the threshold, thereby leading to thyroid growth, or goiter, as the gland is stimulated by the pituitary gland to try to compensate for the deficiency of thyroid hormone production. Circulating iodine is actively concentrated in the thyroid follicular cell by the sodium-iodide symporter, which is a 13-member transmembrane protein located at the junction between the circulation and the thyroid follicular cell. After iodine enters the cell, it moves to the apical membrane where it is effluxed into the colloid space by specific transporters. When it is out of the thyroid follicular cell, iodide is oxidized by the enzyme thyroid peroxidase, which requires the production of hydrogen peroxide in the colloid space. The oxidized iodide is then coupled to tyrosyl residues present on the 660-KD protein thyroglobulin. Specific residues on thyroglobulin can either be monodeiodinated or diiodinated, thereby allowing for the formation of T_4 or T_3. When it is back in the thyroid follicular cell, the thyroglobulin backbone is lysosomally digested, and mature thyroid hormones are secreted into the blood stream. The human thyroid secretes T_4 and T_3 in a ratio of 14:1. Genetic defects in any of the key enzymatic processes (e.g., mutations in thyroid peroxidase) can lead to congenital hypothyroidism (E-Fig. 207-1).

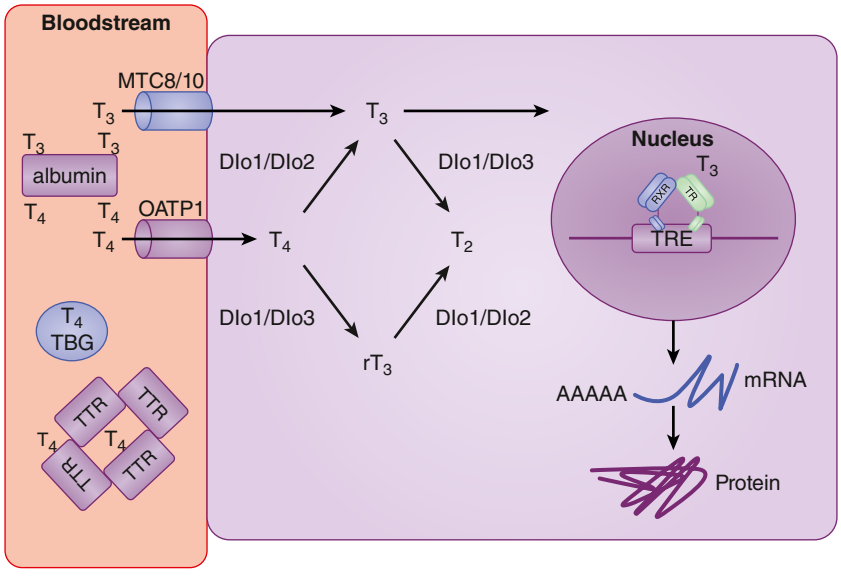
Thyroid Hormone Transport and Metabolism

Once secreted, circulating T_4 and T_3 are tightly bound to plasma proteins, especially thyroxine binding globulin. The ratio of T_4 to T_3 in the circulation is 60:1 because T_4 is more tightly bound to thyroxine binding globulin and thus has a longer half-life than T_3 (5 to 7 days compared with about 24 hours). To mediate their genomic effects, thyroid hormones first enter target cells via specific thyroid hormone transporters that are differentially expressed across cells.[2] The most well known of these transporters is the monocarboxylate 8 transporter, which is mutated in Allen-Herndon Dudley syndrome, a rare X-linked neurologic syndrome of devastating consequences caused by the inability of thyroid hormones to cross the blood-brain barrier in utero. In addition to allowing the transport of thyroid hormones into cells, the monocarboxylate 8 transporter is also responsible for allowing T_4 to be secreted by the thyroid follicular cell into the circulation.

After thyroid hormones enter target cells, local T_3 availability is regulated by a family of deiodinases that can either activate T_4 to T_3 or inactivate T_4 to the inert reverse T_3 or inactivate T_3 to T_2. The deiodinase family contains three members. Type 1 deiodinase is highly expressed in the liver, has both activating and inactivating properties, but preferentially converts T_4 to T_3. Type 2 deiodinase, which also is an activating deiodinase, is highly expressed in the pituitary, central nervous system (CNS), and skeletal muscle. In contrast, type 3 deiodinase is an inactivating enzyme that is highly expressed during development in the CNS and in sensory organs (E-Fig. 207-2).



E-FIGURE 207-1. **The thyroid follicular cell: Thyroid hormone synthesis occurs in the follicular cell and requires the uptake of iodine through the sodium-iodine symporter (see text).** T_3 = triiodothyronine; T_4 = thyroxine; TG = thyroglobulin; TPO = thyroid peroxidase.



E-FIGURE 207-2. **Thyroid hormone action: Cellular thyroid hormone action depends on the uptake of T_4 (thyroxine) and T_3 (triiodothyronine) from the circulation where deiodinases control the intracellular levels of T_3.** T_3 has its principal actions in the nucleus where it regulates gene expression via thyroid hormone receptors (TR). Dio = deiodinase; RXR = retinoid X receptor; TBG = thyroid-binding globulin; TRE = thyroid hormone response elements; TTR = transthyretin. (From Mendoza A, Hollenberg AN. New insights into thyroid hormone action. *Pharmacol Ther.* 2017;173:135-145.)

ABSTRACT

The thyroid gland synthesizes both T_4 and T_3, which are essential for normal human growth and development and for normal physiologic function during adult life. Thyroid hormone levels are genetically set in each individual and are regulated by a negative feedback loop that allows for exquisite control. Disorders of thyroid hormone production, including both hypothyroidism and hyperthyroidism, have diverse causes, are exceedingly common, and present important therapeutic challenges for clinicians who are caring for these patients. Thyroid nodules, which have the potential to be malignant, are extremely common in the general population. A systematic approach is critical to discern which nodules must be evaluated further but also to avoid unnecessary therapy, including thyroid surgery.

thyroid cancer

Thyroid Hormone Set Points

Circulating levels of thyroid hormones are the tip of the iceberg, because variations in both transport and deiodination can substantially alter intracellular concentrations of T_3. Nevertheless, the amount of circulating thyroid hormone is controlled tightly by the hypothalamic-pituitary thyroid axis, by which negative feedback of thyroid hormones determines the appropriate set point (E-Fig. 207-3). In the paraventricular nucleus of the hypothalamus, the tripeptide thyrotropin-releasing hormone (TRH) is synthesized and released via the median eminence to the pituitary, where it targets pituitary thyrotropes to synthesize and release thyroid-stimulating hormone (TSH). TSH is released into the circulation, where it binds to its receptor on thyroid follicular cells to stimulate the production of thyroid hormone. Critically, circulating T_4 and T_3 feed back at the level of the hypothalamus to regulate the production of TRH and at the level of the pituitary to regulate the synthesis and secretion of TSH. In this way, TSH levels rise when thyroid hormone levels are low and are suppressed when thyroid hormone levels are high, thereby making TSH the most useful screening test for disorders of thyroid function. Importantly, TSH and thyroid hormone levels remain quite constant through a person's lifetime, thereby suggesting a genetic set point for the thyroid axis.

T_3 engages its cognate nuclear receptors, which are members of the nuclear receptor family that includes receptors for vitamin D, estrogen, and androgen. All members of the family possess a modular structure that includes a DNA-binding domain and a specific ligand or hormone binding domain. The three thyroid hormone receptor isoforms have similar functions, but their actions differ based on where they are expressed. For example, TRβ2 is highly expressed in the hypothalamus and pituitary, where it controls the secretion of TSH, whereas TRβ1 is the principal isoform expressed in the liver, where it regulates the metabolism of cholesterol and fatty acids. In contrast, TRα1 is expressed in the heart, the gastrointestinal tract, and bone, where it is an important regulator of cardiac function, heart rate, intestinal motility, bone metabolism, and growth. Patients with TRβ mutations present with inappropriately high thyroid hormone levels because they cannot properly regulate the secretion of TSH. In contrast, patients with TRα mutations have a normal HPT axis but have issues with bone length and gastrointestinal motility, and they are relatively bradycardic.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with thyroid disease can present with symptoms or signs of hyperthyroidism, hypothyroidism, or a goiter. Oftentimes, however, the first manifestation is an abnormal thyroid function test or a palpable goiter or one or more thyroid nodules.

Physical Examination

Physical examination of the thyroid gland starts with an inspection of the appearance of the anterior neck for visible thyroid nodules, goiter, deviation, or lymphadenopathy. The patient should be seated or standing with the neck in a neutral position. The lower anterior neck between the cricoid cartilage and the suprasternal notch is then palpated using the fingertips, with the examiner standing either in front of or posterior to the patient. When using an anterior approach, all four fingers of the right hand are used to palpate the right thyroid lobe, whereas the left thyroid lobe should be palpated with the fingers of the left hand. The size and symmetry of the gland should be noted. A normal thyroid is symmetric, nontender, weighs 10 to 20 grams, has a soft (rather than rubbery or firm) texture, and should move upward with swallowing. The size, location, texture, tenderness, and mobility of any thyroid nodules should be determined, and the presence of cervical lymphadenopathy should be assessed. To gauge the presence of a substernal goiter in the setting of thyroid enlargement or when the inferior margins of the gland cannot be palpated, the patient should be asked to raise both arms with forearms against the side of the face. Substantial substernal extension of the thyroid will cause narrowing of the thoracic inlet when the goiter shifts upward, thereby resulting in the rapid development of facial plethora and distention of the neck veins. In some patients with a diffuse goiter from Graves disease, increased thyroid vascularity causes an audible bruit over the thyroid gland on auscultation.

Laboratory Testing

Serum TSH is a sensitive screening test for primary thyroid dysfunction and should be obtained in all patients who have symptoms or signs that are concerning for thyroid disease. The reference range for the serum TSH level is typically approximately 0.5 to 4.5 mIU/L, but it is lower (about 0.1 to 4.0 mIU/L) in early pregnancy.[3] Serum TSH values also may increase somewhat with normal aging, but age-specific TSH reference ranges have not been defined. Serum TSH levels alone cannot be used to diagnose thyroid gland dysfunction in the presence of pituitary disease (Chapter 205).

Although subtle shifts in thyroid function are better detected by serum TSH values than by levels of peripheral thyroid hormones, measurement of peripheral thyroid hormones is needed to determine the degree of thyroid dysfunction when the serum TSH level is abnormal. The vast majority (>99%) of circulating T_4 and T_3 is bound to thyroxine binding globulin (TBG) and other binding proteins, and it is only the tiny unbound (free) fraction that is bioactive. Commercial assays for free T_4 are reliable in most settings. However, accurate measurement of free T_3, which is present at much lower levels, is challenging, so total T_3 levels are often used instead. Overt hypothyroidism is defined as an elevated serum TSH level with a low free T_4 level, and subclinical hypothyroidism is defined as an elevated serum TSH level with a normal free T_4 level.

Measurement of both T_3 and free T_4 is useful in the evaluation of potentially thyrotoxic patients. Overt hyperthyroidism is defined as a low serum TSH level with elevated peripheral thyroid hormone levels, whereas subclinical hyperthyroidism is defined as a low serum TSH level with normal peripheral hormone levels. In Graves disease and nodular autonomy, the thyroid gland often preferentially secretes T_3, so the ratio of circulating T_3 : T_4 is higher (above 20:1) than in thyroiditis, where the lower T_3 : T_4 ratio reflects the ratio of hormones stored in the thyroid gland. However, a number of conditions and medications can interfere with the results of thyroid function tests (Table 207-1).[4]

The presence of elevated TSH receptor stimulating antibody titers is highly sensitive and specific for the diagnosis of Graves disease. Elevated levels of serum thyroperoxidase and thyroglobulin antibody may be useful to confirm the diagnosis of autoimmune thyroiditis. Serum thyroglobulin is useful as a tumor marker for differentiated thyroid cancers, as is the serum calcitonin level for medullary thyroid cancer. The erythrocyte sedimentation rate is used in the diagnosis of subacute thyroiditis.

Imaging

Ultrasonography, which is the best imaging modality for evaluating thyroid structure,[5] can' determine the thyroid gland's size and echotexture. For example, the thyroid gland has a distinctively heterogeneous echotexture in individuals who have autoimmune thyroiditis, whereas vascularity as assessed by Doppler ultrasonography is typically increased in Graves disease and absent in inflammatory thyroiditis. Ultrasonography also can characterize the size and location of thyroid nodules, as well as whether they are solid or cystic. Although thyroid malignancy usually cannot be diagnosed based on ultrasound alone, ultrasonographic risk stratification (based on the size, shape, echogenicity, and margins of the nodule, as well as the presence of microcalcifications) can guide decision making regarding the need for fine-needle aspiration biopsy. Ultrasound is also a sensitive tool for assessing cervical lymphadenopathy. Other forms of anatomic imaging, including computed tomographic (CT) scans and magnetic resonance imaging (MRI), are less frequently used to assess the thyroid gland, but they may be helpful in establishing the presence of a substernal goiter or determining whether a goiter is causing tracheal narrowing. Positron emission tomography (^{18}FDG-PET) scanning may be used to localize metastatic thyroid cancer.

Although radioactive iodine-123 (I^{123}) uptake scanning can differentiate among various causes of thyrotoxicosis (e.g., I^{123} uptake is diffusely increased in Graves disease but is low or absent in inflammatory thyroiditis), highly sensitive and specific TSH receptor-stimulating antibody assays have largely replaced scanning for this indication. However, I^{123} scanning is still used to distinguish among hyperfunctioning ("hot"), hypofunctioning ("cold"), or isofunctioning nodules. I^{123} scans also are useful in patients with hyperthyroidism when the physical examination or ultrasound findings indicate the presence of thyroid nodularity. In addition, whole-body I^{123} scans may be used in patients with thyroid cancer to identify recurrent or metastatic disease. Radioactive iodine scanning is not effective in the setting of a recent large iodine load (e.g., from exposure to iodinated contrast media) because the gland will already be saturated with non-radioactive iodine so the uptake of the I^{123} will be low. In this setting, pertechnetate scanning is an alternative. The use of all thyroid scintigraphy is contraindicated during pregnancy.

Differential Diagnosis

The diagnosis of hypothyroidism (Table 207-2), hyperthyroidism (Table 207-3), or a thyroid nodule must prompt a search for the specific cause. Of note is that some conditions (e.g., various forms of thyroiditis) can cause transient hyperthyroidism followed by hypothyroidism. Goiters can be associated with hyperthyroidism (e.g., Graves disease, toxic multinodular goiter) or hypothyroidism (e.g., iodine deficiency) or be seen in euthyroid patients.

TABLE 207-1 CAUSES OF SPURIOUS OR MISLEADING THYROID FUNCTION TESTS

CAUSE		THYROID FUNCTION TEST EFFECT
Laboratory artifacts	**Biotin** (in some assays, in patients taking biotin doses >100 mg/day)	Artifactually decreased TSH and increased free and total T_4 and T_3. Results normalize after stopping biotin. supplements for 2-3 days.
	Heterophile antibody	Artifactually increased TSH. No effect on T_4 or T_3. Most assays incorporate blocking agents to eliminate this interference.
	Thyroid hormone autoantibody	Artifactually increased total and free T_4 and/or T_3. No effect on TSH. If suspected, compare against measurements by equilibrium dialysis.
	Macro TSH (large bioinactive circulating form of TSH composed of TSH complexed with autoimmune anti-TSH antibodies)	Artifactually elevated TSH. No effect on T_4 or T_3. If suspected, polyethylene glycol can be used in the laboratory to precipitate the macro TSH.
Alterations in thyroid hormone binding	**Increased thyroxine binding globulin levels** • Hepatitis • Pregnancy • Hereditary TBG excess • Medications: *oral estrogens, selective estrogen receptor modulators, mitotane, opiates, 5-flurourcil*	Elevated total, but not free, T_4 and T_3 levels. No effect on TSH.
	Increased binding to albumin • Familial dysalbuminemic hypothyroxinemia (rare, autosomal dominant disorder)	Elevated total and sometimes free T_4. T_3 unaffected. No effect on TSH.
	Decreased thyroxine binding globulin levels • Hereditary TBG deficiency • Medications: *androgens, nicotinic acid, chronic glucocorticoid therapy, danazol, L-asparaginase*	Decreased total, but not free, T_4 and T_3 levels. No effect on TSH.
	Competition with T_4 and T_3 Binding Sites on Thyroid Hormone Binding Proteins • Medications: *Aspirin, salsalate, furosemide (high dose), heparin and low-molecular-weight heparins*	Increased free T_4 and T_3. No effect on TSH.
Inhibition of 5′-deiodination (activation from T_4 to T_3)	**Amiodarone**	Slightly high total and free T_4, slightly low total and free T_3. No effect on TSH.

T_3 = triiodothyronine; T_4 = thyroxine; TBG = thyroid-binding globulin; TSH = thyroid-stimulating hormone.

HYPOTHYROIDISM

DEFINITION

Hypothyroidism refers to conditions in which levels of circulating thyroid hormones are lower than their genetic set point. Hypothyroidism can be classified as primary, when the function of the thyroid gland itself is impaired, or secondary (central), when an abnormality in the pituitary gland's secretion of TSH prevents normal synthesis and secretion of thyroid hormones by the thyroid gland. Primary hypothyroidism is further classified into overt or subclinical hypothyroidism. In overt hypothyroidism, circulating levels of T_4 and T_3 are below normal laboratory cutoffs, the

TSH level is usually above 20 mIU/L, and patients typically manifest some of the symptoms of hypothyroidism. In subclinical hypothyroidism, circulating T_4 and T_3 levels are within the normal range of the general population but, because they are lower than the individual's targeted set point, lead to an elevation of the TSH level (usually less than 10 mIU/L but occasionally as high as 20 mIU/L). Importantly, patients with subclinical hypothyroidism are often identified by routine laboratory testing, not because of clinical symptoms.

EPIDEMIOLOGY

In the United States and Europe, the prevalence of hypothyroidism is about 5% in the general population, with the majority of cases being subclinical hypothyroidism. Additionally, most of the hypothyroidism is primary, with secondary hypothyroidism likely only comprising 1% of all cases. The incidence of hypothyroidism is much higher in women than in men, and the risk increases with age, with women over age 70 years at highest risk. The incidence of hypothyroidism is, not surprisingly, doubled in persons who have another autoimmune disease, given that the most common cause of hypothyroidism is autoimmunity.[6] In the United States, the prevalence of hypothyroidism is highest in Whites and lowest in Blacks.

PATHOBIOLOGY

In 1 per 3500 births, defects in the transcription factors needed for the development of thyroid follicular cells or in the transporters or enzymes needed for the synthesis of thyroid hormone cause congenital hypothyroidism and devastating neurological consequences. Iodine deficiency also can lead to profound hypothyroidism and severe developmental abnormalities, but iodine fortification of food, particularly salt, in most countries has dramatically reduced the prevalence of iodine deficiency.

The most frequent cause of failure of the thyroid gland is an autoimmune disease, Hashimoto thyroiditis, which can occur in isolation or in conjunction with other autoimmune conditions and as a component of polyglandular autoimmune syndromes (Chapter 212). The use of immune checkpoint inhibitors and tyrosine kinase inhibitors also increases the incidence of autoimmune thyroid disease.

Hashimoto thyroiditis is characterized by a lymphocytic infiltration that is mediated by aberrantly activated T cells and by inflammation and fibrosis, which lead to failure of follicular units. Autoimmune thyroid disease is highly heritable, and gene variants in a variety of immunomodulatory genes lead to increased susceptibility.[7] The T-cell immune attack on the thyroid also leads to the measurable production of antibodies directed against both thyroid-peroxidase and thyroglobulin. However, although the titer of these antibodies can be helpful in predicting the progression from mild to severe thyroid failure, these autoantibodies themselves do not appear to be the cause of Hashimoto thyroiditis because they can also be found in patients without thyroid dysfunction.

Another common cause of primary hypothyroidism (see Table 207-2) is thyroid surgery for thyroid nodular disease, cancer, or Graves disease. Even removal of only one lobe of the thyroid can lead to hypothyroidism in a small proportion of patients, especially in the presence of antithyroid-peroxidase or antithyroglobulin antibodies. The thyroid also can be damaged by parathyroid surgery or in other significant head and neck surgery procedures. Radioactive iodine therapy for Graves disease is a frequent cause of hypothyroidism, and external beam radiotherapy for head and neck cancer can also destroy the thyroid unless it is specifically protected.

Both painless and subacute thyroiditis can lead to permanent hypothyroidism. Rarer causes of primary hypothyroidism include infiltrative diseases such as Reidel thyroiditis, which is characterized by a fibrous infiltration of the thyroid gland, sometimes with extension to the recurrent laryngeal nerve or the parathyroid glands. Hemochromatosis (Chapter 196) and amyloidosis (Chapter 174) can cause primary hypothyroidism by infiltrating the thyroid gland.

Drugs can lead to hypothyroidism by affecting the synthesis of thyroid hormone. Amiodarone, which is likely the most common agent to affect the thyroid, can cause both hypothyroidism and thyrotoxicosis. Its induction of hypothyroidism is because the large amounts of iodine contained in the drug stimulate the gland reflexively to decrease the synthesis of thyroid hormone. Amiodarone-induced hypothyroidism can be permanent, especially in patients who have autoimmune thyroid disease. Additionally, amiodarone is an inhibitor of the type 1 deiodinase, so it decreases the conversion of T_4 to T_3.[8] Lithium therapy can also lead to hypothyroidism by affecting the synthesis and release of thyroid hormone.

Acquired secondary or central hypothyroidism (see Table 207-2) is most commonly due to a pituitary tumor, either a primary adenoma or metastatic tumor, that impairs the function of the pituitary cells that synthesize TSH. In these conditions, other pituitary hormones are also affected, so hypothyroidism is essentially always accompanied by hypogonadism and adrenal insufficiency (Chapter 205). Tumors that invade the hypothalamus (Chapter 204) can impair the release of TRH, impair the production of TSH, and thereby reduce the production of thyroid hormone. Infiltrative diseases such as sarcoidosis (Chapter 83) can impair the hypothalamic-pituitary TSH-producing axis. Radiation therapy to the area can also lead to pituitary failure. The anticancer agent bexarotene is a retinoid that directly inhibits the synthesis of TSH and causes central hypothyroidism.

CLINICAL MANIFESTATIONS

Overt hypothyroidism with frankly low thyroid hormone levels and subclinical hypothyroidism may be associated with few symptoms, and the diagnosis is often made by the appearance of a mildly elevated TSH on routine blood work. The clinical manifestations of hypothyroidism are nonspecific, highly variable, and most dependent upon the degree of decrease in the levels of circulating thyroid hormones. Overt hypothyroidism is characterized by symptoms of fatigue, lethargy, weight gain, a decrease in mental acuity, cold intolerance, hair loss, and dry skin in both men and women. Women can have menstrual irregularities, most commonly prolonged heavy menses. The disease can be present for a long period before diagnosis, and the appearance or recognition of new symptoms can be difficult.

The physical findings in hypothyroidism can be myriad and relate to the cause and degree of hypothyroidism. An elevated TSH level leads to an enlarged thyroid gland, except in some individuals with Hashimoto and Riedel thyroiditis, in which the gland may be small because of fibrosis. Bradycardia may be detected, and diastolic hypertension can be seen. Hypothermia usually is present only in severe hypothyroidism. Other classic signs of hypothyroidism include loss of the outer eyebrows and general hair loss or thinning. The skin may be dry and cool, and nonpitting edema may be present peripherally. Delayed return of deep tendon reflexes is considered the most sensitive clinical finding in hypothyroidism and is probably best assessed using the ankle jerk reflex. The nails may be brittle. In severe hypothyroidism, a pericardial effusion (Chapter 62) can be present, so muffled heart sounds may be noted on the physical examination. Because of the chronic nature of the effusion, signs or symptoms of pericardial tamponade (Chapter 62) are distinctly unusual.

If thyroid hormone levels are profoundly reduced for a long period of time or if patients experience a secondary systemic insult, significant hypothermia, hypotension, bradycardia, and profound neurologic manifestations, including coma, can be seen. This syndrome, which is termed myxedema coma, is a medical emergency.

In addition to abnormalities on thyroid function testing, hypothyroidism can be associated with other suggestive laboratory findings. Probably most sensitive is an unexplained elevation in the serum cholesterol level (Chapter 190), and in particular the low-density lipoprotein (LDL) fraction, given the major role of thyroid hormone signaling in regulating cholesterol metabolism. Significant hypothyroidism can be associated with a macrocytic anemia (Chapter 145), and hypothyroidism should be in the differential diagnosis whenever a patient has an elevated mean corpuscular volume. Hyponatremia (Chapter 102) can also be seen because thyroid hormones are needed for free water clearance. The muscle dysfunction of hypothyroidism may be associated with otherwise unexplained elevations in serum levels of creatine kinase and aspartate aminotransferase.

DIAGNOSIS

The biochemical diagnosis of primary hypothyroidism is heralded by a TSH level that is above the laboratory's normal range, which is usually greater than 4.5 mU/L. An elevated TSH level always warrants measurement of circulating thyroid hormone levels, especially a free T_4 level (Fig. 207-1). Rarely, both the TSH and the free T_4 are elevated, thereby suggesting either peripheral resistance to thyroid hormone or a TSH-secreting pituitary tumor. If the TSH is only mildly elevated (between 4.5 and 20 mU/L), the free T_4 can be within the normal limits, and the diagnosis is subclinical hypothyroidism. If the TSH level is elevated and the free T_4 level is low, the diagnosis is almost always overt primary hypothyroidism.

Once the biochemical diagnosis of primary subclinical hypothyroidism or overt hypothyroidism is made, the physical examination often can establish a presumptive diagnosis. Primary hypothyroidism should be considered in

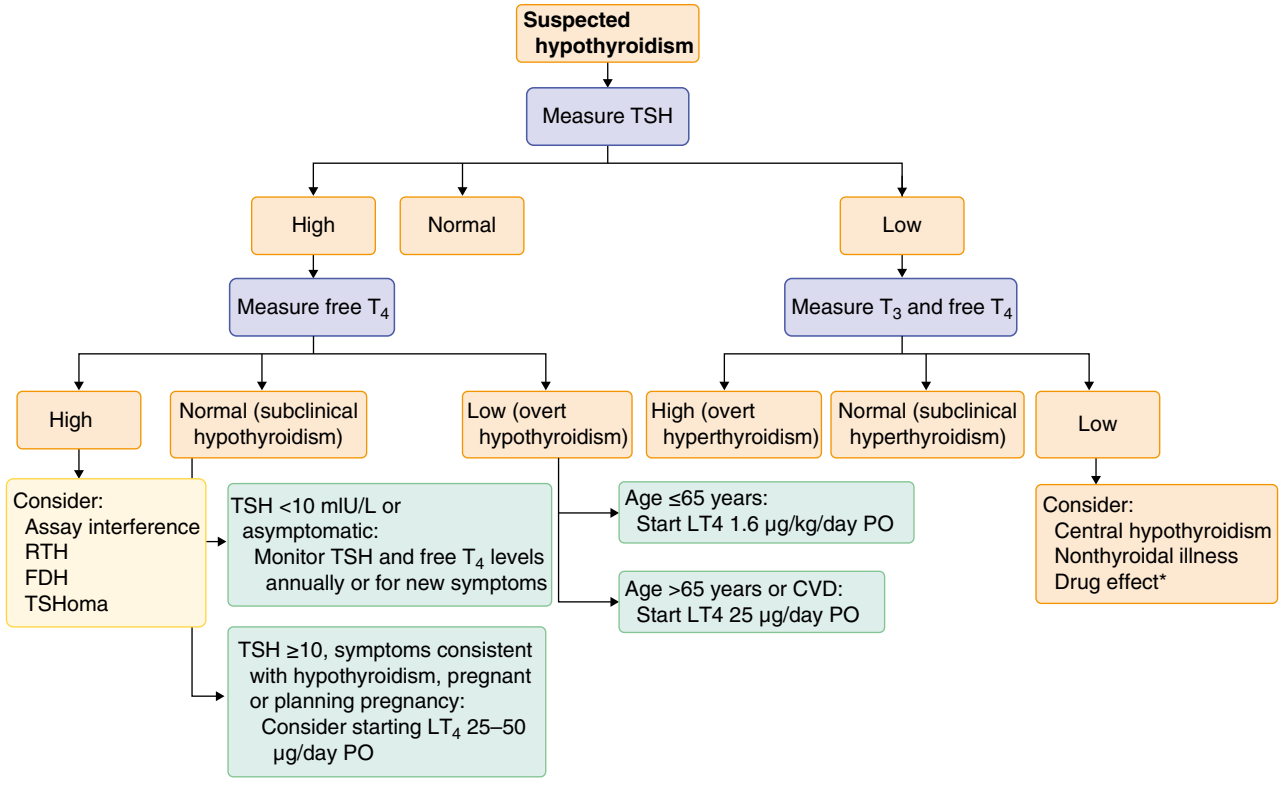

FIGURE 207-1. Evaluation of suspected hypothyroidism. *For example, suppression of TSH by dopamine, lowering free T_4 due to increased metabolism by antiseizure medications. CVD = cardiovascular disease; FDH = familial dysalbuminemic; LT_4 = L-thyroxine; PO = orally; RTH = resistance to thyroid hormone; T_3 = triiodothyronine; T_4 = thyroxine; TSH = thyroid stimulating hormone; TSHoma = TSH-secreting pituitary adenoma.

patients who have another autoimmune disease. The thyroid gland may be either enlarged or nonpalpable in Hashimoto thyroiditis, which is the most common cause. Antithyroid peroxidase or antithyroglobulin antibodies can often confirm the diagnosis of Hashimoto thyroiditis, but they are not positive in all cases.[9] Higher titers of antithyroid peroxidase or antithyroglobulin antibodies often may be helpful in predicting which cases of subclinical hypothyroidism will progress to overt hypothyroidism. By comparison, iodine deficiency is associated with a palpable goiter.

The classic finding in secondary hypothyroidism is a low, normal, or just mildly elevated TSH level despite low circulating levels of free T_4. If such patients have no history of a mass, surgery, or radiation therapy to the area of the hypothalamus or pituitary gland, it is reasonable to obtain a pituitary MRI and to measure other hormone levels.

TREATMENT

Overt Hypothyroidism

L-Thyroxine (which is available in tablets of 25 µg, 50 µg, 75 µg, 88 µg, 100 µg, 112 µg, 125 µg, 137 µg, 150 µg, 175 µg, 200 µg, and 300 µg) is typically prescribed because its long half-life allows for stable dosing and a constant supply of T_4, which can then be converted to T_3 within the circulation and in target cells. Combination T_4/T_3 therapy more closely simulates normal physiology, but current guidelines recommend against its use.

The goal of therapy in primary hypothyroidism is to return the TSH level to the normal range, unless TSH should be suppressed, as in aggressive thyroid cancers. The average required dose of L-thyroxine is 1.6 ug/kg. A major concern is that the bioavailability of L-thyroxine varies among formulations, so patients should try to remain on the same formulation if possible. If the formulation is switched, a TSH level should be evaluated 6 weeks after the change. L-Thyroxine should be taken on an empty stomach, because it is absorbed in the small intestine, where food may impair absorption. A number of other medications (Table 207-4), including iron tablets and calcium carbonate, can impair the absorption of L-thyroxine, so a spacing of a few hours is recommended between L-thyroxine and any of these medications. Very rarely, L-thyroxine can be malabsorbed, but the usual explanation for a poor response is nonadherence.

L-Thyroxine dosing can usually be begun at the predicted weight-based dose, with its effectiveness assessed by changes in clinical signs and symptoms, and by measuring the TSH level no earlier than the interval required for it to reach its new steady state (5 weeks after beginning the medication or after a change in dose). Aging is associated with a decreased L-thyroxine requirement, probably due to decreased tissue demand both centrally and peripherally. In patients in whom an increase in energy expenditure or demand could cause issues, in particular in older patients or in patients who have significant coronary artery disease, a smaller starting dose (i.e., 25 µg) should be chosen, and careful uptitration can be undertaken with changes to the dose every 6 weeks.

The most common problem with L-thyroxine is over-replacement that leads to mild hyperthyroidism with a suppressed TSH level. In patients who have secondary hypothyroidism and in whom the TSH level cannot be used as a measure of efficacy, a reasonable practice is to titrate the dose based on the free T_4 and aim for it to be in the upper half of the normal range.

TABLE 207-4 INTERFERENCE WITH THYROXINE REPLACEMENT THERAPY

FACTORS CONTRIBUTING TO UNDERREPLACEMENT
Inadequate prescribed dose
Limited compliance
Decreased absorption due to ingestion of agents that bind thyroxine
Ferrous sulfate
Calcium carbonate
Aluminum hydroxide
Sucralfate
Cholestyramine
Soy protein
Increased metabolism of thyroxine
Pregnancy
Drugs
Phenytoin
Phenobarbital
Carbamazepine
Rifampin
Diminishing residual thyroid function
Changing formulations
FACTORS CONTRIBUTING TO OVERREPLACEMENT
Excessive prescribed dose
Factitious ingestion of additional doses
Decreased metabolism of thyroxine due to aging
Increasing residual thyroid function
Changing formulations

Combination T_4/T_3 Therapy

Although the vast majority of patients treated with L-thyroxine do well, up to 15% of patients experience persistent symptoms of hypothyroidism despite normal TSH levels. Because the thyroid gland secretes both T_4 and T_3 and because L-thyroxine monotherapy results in low T_3 levels, some patients may have cellular hypothyroidism despite a normal TSH level. Although more than a dozen randomized trials have failed to show a benefit of combination therapy compared with L-thyroxine monotherapy, uncertainty persists regarding the potential benefit of combination therapy specifically in patients who are dissatisfied with monotherapy, especially if T_3 and T_4 are administered in their ideal physiologic ratios. If combination therapy is used, the dose of L-thyroxine should be decreased and replaced by 2.5 to 10 μg of T_3 daily, ideally given as a divided dose twice daily.[10]

Subclinical Hypothyroidism

Although the treatment of overt hypothyroidism with L-thyroxine is clearly beneficial, the benefit of treatment is uncertain in patients who have mildly elevated TSH levels but a normal free T_4 level.[A1–A3] For example, the treatment of subclinical hypothyroidism does not improve symptoms or quality of life in persons over age 65 years. In large population-based studies, however, L-thyroxine appears to be beneficial if the TSH level is above 10 mU/L, perhaps in part because it lowers LDL cholesterol levels.[A4] One approach is to defer treatment and recheck the TSH and free T_4 levels annually. Another is to treat individuals who have TSH levels greater than 10 mU/L or have elevated serum LDL cholesterol levels. A third approach is to treat individuals whose TSH level is in the 5 to 10 mIU/L range if they have symptoms potentially attributable to hypothyroidism or elevated titers of thyroid peroxidase antibodies.

Myxedema Coma

Because of the high mortality associated with myxedema coma, treatment with parental L-thyroxine is imperative. The usual approach is an intravenous loading dose of 200 to 300 μg followed by 1.6 μg/kg intravenously every 24 hours. Since the conversion of T_4 to T_3 may be impaired, parenteral T_3 (5 to 10 μg T_3 every 8 to 12 hours) may be added until clinical improvement is seen. High-dose glucocorticoids (100 mg of hydrocortisone every 6 hours until adrenal insufficiency is excluded) are usually added prior to starting L-thyroxine because of the concern of associated adrenal insufficiency. Hypothermia should be treated with passive rather than active rewarming to prevent further hypotension.

Pregnancy

The required dose of L-thyroxine increases during pregnancy (Chapter 221) because of an increase in thyroxine binding globulin, fetal demand (especially during the first trimester), and placental metabolism of thyroid hormones.[11] In euthyroid pregnant patients, human chorionic gonadotropin acts as a TSH receptor stimulator and allows the endogenous thyroid to increase production of thyroid hormones. If the pregnant patient has no thyroid reserve (i.e., a surgically removed thyroid gland), then a dose adjustment of up to 33 to 50% of the baseline dose may be required. If partial thyroid reserve is present (i.e., some patients with Hashimoto thyroiditis), a dose increase of 25% may be necessary. Because undetected hypothyroidism in early pregnancy has been linked to poorer fetal neurologic outcomes, it is important to increase the L-thyroxine dose as soon as pregnancy is confirmed. A simple approach is to increase the thyroxine dose from 7 tablets to 9 tablets weekly (i.e., add a second tablet on two of the days of the week). The TSH level can be evaluated 3 weeks later to ensure that it is in the target range (<2.5 mIU/L during gestation) and should be monitored every 4 weeks until mid-gestation.

PROGNOSIS

Treatment of hypothyroidism with L-thyroxine is highly effective. Once an ideal dose is found and the TSH level is normalized, patients can be followed annually with a TSH level to ensure stability. Patients should be counseled continually regarding taking their L-thyroxine on an empty stomach and being aware of other medications that can impair its absorption. Additionally, women who are considering pregnancy must know to contact their physician to increase their L-thyroxine dose and be monitored closely as soon as they know they are pregnant.

HYPERTHYROIDISM

DEFINITION

Hyperthyroidism is a clinical syndrome in which circulating thyroid hormone levels are either frankly elevated, and thereby suppress TSH levels, or are within the normal range but are too high for that person's set point, thereby at least partially suppressing TSH levels. The latter syndrome is termed subclinical hyperthyroidism. The degree of signs and symptoms depend on the cause of the hyperthyroidism as well as on the levels of circulating T_4 and T_3. Importantly, hyperthyroidism includes all syndromes related to the endogenous overproduction of thyroid hormone by the thyroid gland, whereas thyrotoxicosis includes all causes of elevated thyroid hormone levels.

EPIDEMIOLOGY

The prevalence of hyperthyroidism is 1 to 2% in women and 0.1 to 0.2% in men, including both overt and subclinical hyperthyroidism. In younger populations (ages 12 to 49 years), the prevalence of hyperthyroidism is higher in Black persons as compared with White or Hispanic persons. Graves disease, which is the most common cause of hyperthyroidism, is four-fold more common in women. Its environmental triggers may include iodine, smoking, stress, and potentially infection because epitopes on *Yersinia enterolitica* (Chapter 288) overlap with that of the TSH receptor. Additionally, drugs (e.g., interferon-α and immune checkpoint inhibitors) and the recovery from lymphopenia seen in immune reconstitution inflammatory syndrome (Chapter 357) can lead to Graves disease. Genetic predisposition is limited to autoimmune susceptibility genes. Long-standing iodine deficiency is associated with higher rates of toxic nodular goiter.

PATHOBIOLOGY

Thyrotoxicosis can result from the overproduction and release of thyroid hormones directly from the gland itself, from an ectopic source, or from exogenous ingestion of thyroid hormone (see Table 207-3). The release of thyroid hormones from the gland itself can be due to intrinsic synthesis of excess thyroid hormone independent of TSH stimulation, excess release of stored hormone from the thyroid gland because of inflammatory thyroiditis, excess TSH, or the stimulation of the thyroid gland by substances other than TSH, as occurs during pregnancy when elevated levels of human chorionic gonadotropin bind to the TSH receptor on the follicular cell.

Graves disease is caused when a circulating antibody binds to and activates the TSH receptor, thereby leading to growth of the gland and overproduction of T_4 and T_3. These antibodies can also target antigens behind the eye and in skin, thereby leading to ophthalmopathy and pretibial myxedema. In addition to thyrotropin receptor autoantibodies, many patients with Graves disease will also have antithyroid peroxidase and antithyroglobulin antibodies, thereby indicating an overlap in immune dysregulation between Graves and Hashimoto diseases.

During pregnancy, the human chorionic gonadotropin–mediated rise in thyroid hormone levels in the first trimester is necessary to meet fetal demand and to maintain stable levels of free thyroid hormones in the setting of excess thyroxine-binding globulin. A potential side effect, however, is that excess thyroid stimulation, especially coincident with hyperemesis gravidarum, can lead to significant clinical hyperthyroidism (Chapter 221).

Thyroid nodular disease can also lead to hyperthyroidism. Solitary nodules can have mutations in the TSH receptor or its downstream components, thereby leading to constitutive activation, nodular growth, and hyperthyroidism. A multinodular gland can also cause hyperthyroidism, especially in the presence of excess iodine, which often results from the use of contrast agents or amiodarone. Finally, rare TSH-producing pituitary adenomas can lead to hyperthyroidism with a TSH level that is inappropriately normal or elevated.

Exogenous causes of thyrotoxicosis include ectopic production of T_4 and T_3 in rare ovarian teratomas (termed struma ovarii) or from widely metastatic follicular thyroid carcinoma. Most commonly, however, exogenous thyrotoxicosis is secondary to over-replacement with thyroid hormone preparations or the ingestion of food (e.g., hamburger thyrotoxicosis from improperly processed meat) or supplements that contain excessive thyroid hormones.

The symptoms and signs of hyperthyroidism are directly attributable to the effects of thyroid hormones on target cells via their genomic and nongenomic actions, including activation of the sympathetic nervous system,[12] the cardiovascular system, and the systems that regulate energy expenditure. Thyroid hormones likely activate pathways that mediate activation of the adrenergic response. Thyroid hormones also have a catabolic effect on muscle.

CLINICAL MANIFESTATIONS

The clinical presentation of hyperthyroidism depends on both the level of circulating thyroid hormones and the duration of the hyperthyroidism. In mild subclinical hyperthyroidism, patients may have no clinical symptoms, whereas patients with florid Graves disease may develop hemodynamic crisis and even death, often termed thyroid storm. In general, the clinical signs and symptoms of hyperthyroidism are more apparent in younger patients, whereas elderly patients may have "apathetic" hyperthyroidism without classic hyperadrenergic symptoms.

Patients with significant hyperthyroidism often report heat intolerance, weight loss despite a vigorous appetite, palpitations, and a tremor, which may manifest as difficulty with fine motor control, including handwriting. Additional symptoms can include emotional lability, enhanced gastrointestinal motility, diarrhea, and muscle weakness. General signs on physical examination include the presence of tachycardia or atrial arrhythmias, systolic hypertension, a stare and lid lag (when the eye lags behind the upper lid on movement up or down) due to activation of sympathetic tone, tremor, and proximal muscle weakness.

Specific signs that can suggest the cause of hyperthyroidism include thyroid enlargement (goiter), which is diffuse in Graves disease but also can be due to an autonomously functioning single large nodule or multiple nodules. The diffuse enlargement in Graves disease can also be associated with a systolic bruit heard directly over the gland with the bell of the stethoscope. Although all causes of hyperthyroidism can cause lid lag, specific bulging or inflammation around the eyes is distinctive of Graves ophthalmopathy (Fig. 207-2). Similarly, peripheral nonpitting edema or redness on the extensor surfaces of the shins is consistent with pretibial myxedema that is specific to Graves disease. Rarely, clubbing of the nails (Fig. 39-9) and swelling of the distal digits of the hands, termed thyroid acropachy, can also be seen with Graves disease.

FIGURE 207-2. Graves ophthalmopathy. A, A 59-year-old woman with excess proptosis, moderate eyelid edema, and erythema with moderate eyelid retraction affecting all four eyelids. Conjunctival chemosis (edema) and erythema with bilateral edema of the caruncles, with prolapse of the right caruncle, are evident. **B**, A 40-year-old woman with excess proptosis, minimal bilateral injection, and chemosis with slight erythema of the eyelids. On slit lamp examination, she also had evidence of moderate superior limbic keratoconjunctivitis. (From Bahn RS. Graves' ophthalmopathy. *N Engl J Med*. 2010;362:726-738. DIAGNOSIS

Thyroid function testing makes or excludes the diagnosis (Fig. 207-3). In overt hyperthyroidism, both circulating T_4 and T_3 levels will be frankly elevated, whereas the TSH level is completely suppressed. In subclinical hyperthyroidism, circulating T_4 and T_3 levels will be within the normal range, while the TSH level is either fully or partially suppressed. In women of childbearing age, a pregnancy test should be performed to exclude pregnancy-induced hyperthyroidism (Chapter 221).

The absolute levels of total T_4 and total T_3 can also be helpful. For example, Graves disease and nodular thyroid disease are likely to have a T_3 : T_4 ratio of over 20 : 1, whereas the ratio will be less in thyroiditis.

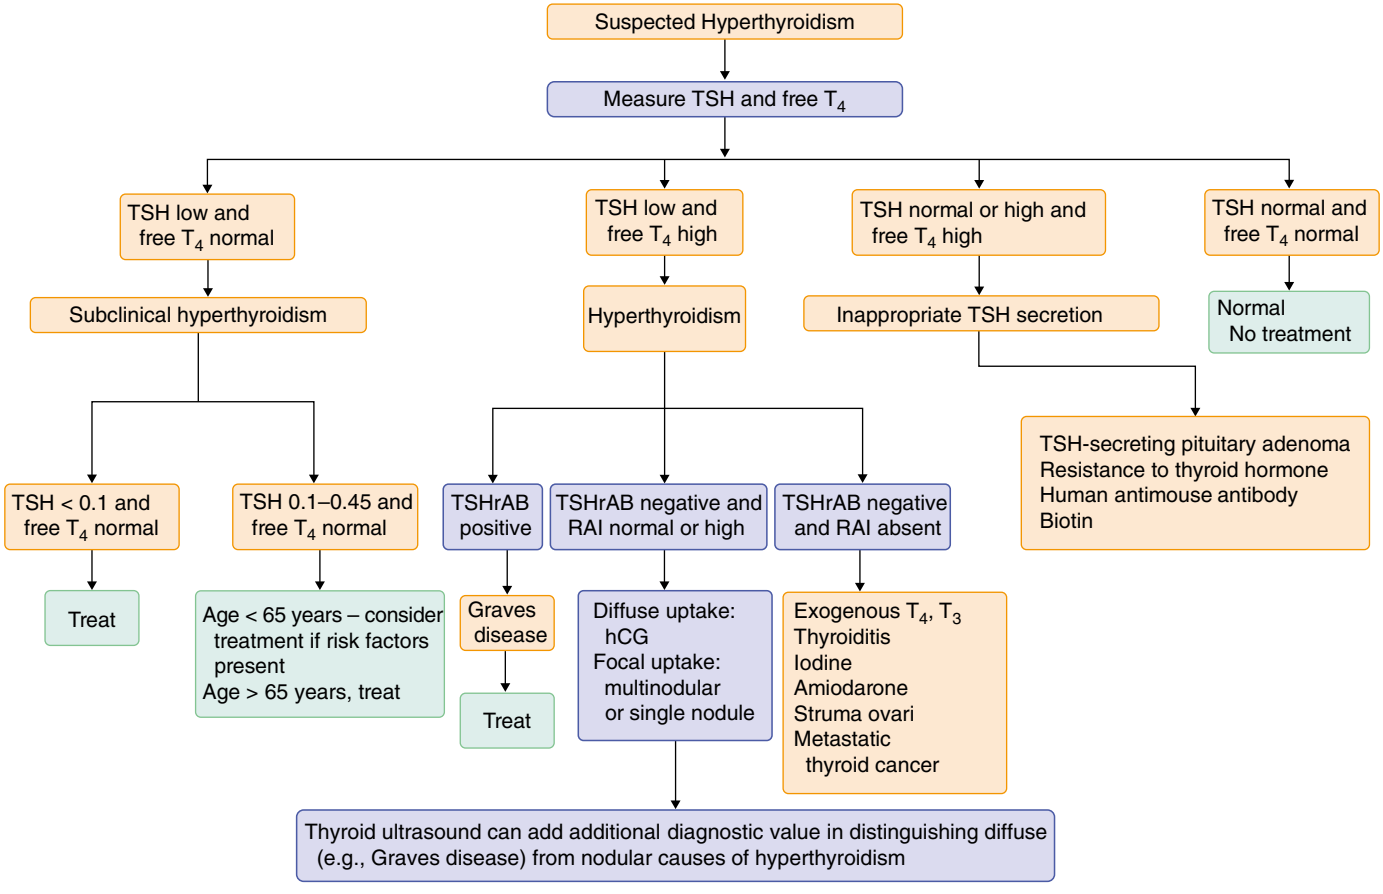

FIGURE 207-3. Algorithm for the assessment of thyrotoxicosis. hCG = human chorionic gonadotropin; RAI = radioactive iodine; T_3 = triiodothyronine; T_4 = thyroxine; TSH = thyroid-stimulating hormone; TSHrAB = TSH-receptor antibodies. (Based on De Leo S, Lee SY, Braverman LE. Hyperthyroidism. *Lancet*. 2016;388:906-918.)

TABLE 207-5 RADIOGRAPHIC EVALUATION OF SUSPECTED THYROTOXICOSIS

ETIOLOGY	FRACTIONAL 24-HOUR RADIOIODINE UPTAKE (%)	THYROID SCAN APPEARANCE
Graves disease	35-95	Diffuse increased homogeneous uptake; visible pyramidal lobe extending from isthmus
Toxic adenoma	20-60	Solitary focus of intense uptake; suppression of uptake in remainder of thyroid
Toxic multinodular goiter	20-60	Patchy heterogeneous foci of increased uptake interspersed with regions of diminished uptake
Subacute thyroiditis	0-2	Minimal to absent uptake
Autoimmune thyroiditis	0-2	Minimal to absent uptake; patchy heterogeneous uptake during recovery
Iodine-induced hyperthyroidism	0-2	Minimal to absent uptake
Exogenous thyroid hormone intoxication	0-2	Minimal to absent uptake
Metastatic differentiated thyroid cancer	0-5	Focal uptake in metastases
TSH-secreting pituitary adenoma	30-80	Diffuse increased homogeneous uptake

TSH = thyroid-stimulating hormone.

TABLE 207-6 TREATMENT OF GRAVES DISEASE

TREATMENT	OUTCOME
Antithyroid drugs: methimazole, propylthiouracil	About 50% remission rate; hypothyroidism unusual
Radioactive iodine (^{131}I)	About 75 to 90% cure rate (euthyroid or hypothyroid) after one dose; up to 80% risk of hypothyroidism at 1 year
Surgical total thyroidectomy	Definitive cure and universal hypothyroidism, except in very rare cases of ectopic thyroid tissue

Adapted from Jonklaas J, Cooper DS. Thyroid. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:1462-1476.

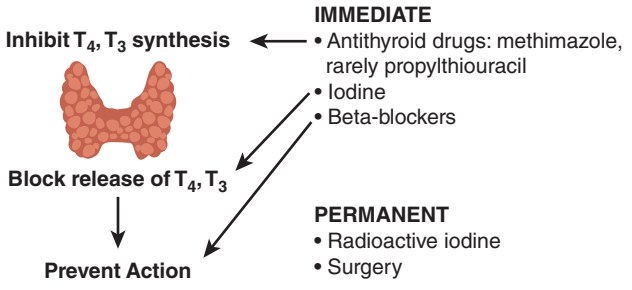

FIGURE 207-4. **Treatment of hyperthyroidism.**

The diagnosis of Graves disease can be confirmed by directly measuring TSH-receptor antibody levels. The uptake of radioactive iodine is useful when the cause of hyperthyroidism otherwise cannot be discerned (Table 207-5). Since the uptake of iodine into the thyroid gland is entirely regulated by TSH, the uptake of radioactive iodine in the thyroid should be close to zero when the TSH level is suppressed, as in thyroiditis or an exogenous or ectopic source of thyroid hormone. In contrast, the uptake of radioactive iodine will be diffusely inappropriately normal or elevated in Graves disease and focally increased in nodular causes of hyperthyroidism, including multinodular goiter and single autonomous nodules. A radioactive iodine scan is unlikely to be helpful in the presence of excess nonradioactive iodine, such as with the administration of amiodarone. Technetium scanning also can show diffuse excess uptake in Graves disease and focal uptake in nodular hyperthyroidism. Thyroid ultrasound can confirm the presence or absence of thyroid nodules and, using Doppler, identify a relative increase in blood flow, which is suggestive of Graves disease and nodular forms of hyperthyroidism.

Laboratory abnormalities associated with hyperthyroidism include elevated liver aminotransferase levels, because excess thyroid hormone signaling increases hepatocyte stress. The alkaline phosphatase level can also be elevated, likely reflecting bone resorption caused by excess thyroid hormones. The serum calcium level can be mildly elevated, sometimes associated with hypercalciuria and even nephrolithiasis (Chapter 111). Graves disease also can present with neutropenia and a lymphocytosis. Because antithyroid drugs used to treat hyperthyroidism can also cause neutropenia and abnormalities in liver enzymes, baseline values should be obtained before starting treatment.

TREATMENT

The treatment of hyperthyroidism (Table 207-6) depends on its underlying cause and severity. However, the basic approach is similar for all causes.

If thyroid hormones are being overproduced by the gland because of Graves disease or other causes, treatment must inhibit the synthesis of thyroid hormone (by removing the gland surgically, by inactivating it biologically with radioactive iodine or antithyroid drugs) potentially coupled with β-adrenergic antagonists to block the peripheral actions of the thyroid hormone if the clinical symptoms are significant. In contrast, if the problem is over-release of preformed thyroid hormone because of damage to the gland, then the only focus should be blocking the actions of thyroid hormones (Fig. 207-4).

Blocking Thyroid Hormone Action

Symptomatic control of the hyperadrenergic and cardiovascular symptoms (e.g., tremor, tachycardia, and the ventricular response rate of atrial fibrillation) of hyperthyroidism can be achieved quickly with nonselective β-blockade. The preferred β-blocker is propranolol, which inhibits type 1 deiodinase and can reduce serum T_3 by 20% at a daily dose of 80 mg. The usual starting dose of propranolol is 20 mg every 6 to 8 hours, depending on the severity of the hyperthyroidism, titrated upwards to a maximum of 240 mg over 24 hours. If propranolol is a concern or causes complications in patients with asthma or chronic obstructive lung disease, selective β-blockers (e.g., atenolol [25 to 50 mg] or metoprolol [25 to 50 mg]) can be used; these drugs do not block the activity of type 1 deiodinase but nevertheless are efficacious for treating the clinical symptoms of thyrotoxicosis.

Reducing Thyroid Hormone Levels

Antithyroid Drugs

The thionamides, methimazole and propylthiouracil, block the activity of thyroid peroxidase and, as a result, the synthesis of thyroid hormone. They may also have immunosuppressive effects, thereby blunting the autoimmune process itself. Propylthiouracil also inhibits the activation of type 1 deiodinase.

Methimazole is the recommended agent of choice for hyperthyroidism except for thyroid storm, when T_3 levels must be lowered quickly, or the first trimester of pregnancy. The usual starting dose is 20 to 30 mg given either once a day or divided into two doses. Propylthiouracil must be given two to three times per day, and 400 mg of propylthiouracil is equivalent to 30 mg of methimazole.

About 1 to 5% of patients on either medication develop a rash or urticaria, which can be treated with the use of an antihistamine (e.g., diphenhydramine 25 to 50 mg) or by switching to the other drug. More rare (about 1/1000 with either drug) is agranulocytosis, which can be idiosyncratic but is more likely in the first few months of therapy, especially in older patients and with higher doses. Monitoring of the neutrophil count is not useful because of the rapidity of onset of the process, so patients should be instructed to stop the drug and call their physician immediately if they develop fever, sore throat, or any other symptoms suggestive of infection. Recovery from the neutropenia is usual, but severe infections may require hospitalization, broad-spectrum antibiotics (Chapter 260), and the administration of growth factors (Chapter 153) to stimulate white cell growth. If this side effect does occur, neither drug can ever be given again. Another rare but serious side effect is fulminant hepatic necrosis, which is seen primarily with propylthiouracil and is a common cause of drug-related liver failure (Chapter 136). Methimazole also can cause a drug-induced hepatitis or, more commonly, cholestasis.

Treatment with methimazole or propylthiouracil will usually lower the T_4 and T_3 levels to normal within 4 to 6 weeks. As the T_4 and T_3 levels fall toward normal, their dose can be titrated down to maintain euthyroidism. The TSH level cannot be used to follow the regression of hyperthyroidism because it may remain suppressed for weeks even after T_4 and T_3 levels fall into the normal range.

In Graves disease, medical antithyroid drug therapy can induce a remission and restore the euthyroid state. If therapy for 12 to 18 months results in normalization of thyrotropin receptor autoantibody levels, remission is likely and medical therapy can be discontinued. If thyrotropin receptor autoantibody levels remain elevated, however, more definitive therapy with radioactive iodine or surgery can be pursued, although another option is to continue medical therapy for several years to see if thyrotropin receptor autoantibody levels eventually return to normal.

Iodine and Other Agents

Supraphysiologic doses of iodine are usually used only after starting antithyroid drug therapy in patients who have severe thyrotoxicosis, but they also can be utilized alone in patients who are intolerant to antithyroid drugs. Iodine is administered as a saturated solution of potassium iodide (SSKI) or as Lugol solution. Lithium also blocks thyroid hormone release and can be utilized short term to control hyperthyroidism in patients intolerant to antithyroid drugs and iodine. Cholestyramine enhances the metabolism of T_4 by the liver and can effectively lower thyroid hormone levels in severe cases.

Radioactive Iodine Therapy

Radioactive iodine kills follicular cells, thereby reducing or eliminating the production of thyroid hormone. Radioactive iodine is highly effective in the treatment of Graves disease, autonomous hyperfunctioning thyroid nodules, and toxic multinodular goiters. The goal of radioactive iodine therapy is to ablate the thyroid gland and cause hypothyroidism. For Graves disease, radioactive iodine ameliorates hyperthyroidism in 90% of patients within 6 months but may increase the risk of cancer slightly.[13] Radioactive iodine may worsen Graves ophthalmopathy and is contraindicated in patients who have significant Graves ophthalmopathy unless patients receive concomitant high doses of corticosteroid therapy for 4 to 6 weeks after the administration of radioactive iodine. Radioactive iodine treatment also may cause radiation thyroiditis and induce the release of preformed thyroid hormone, thereby transiently worsening hyperthyroidism. Pretreatment with an antithyroid drug, to deplete the gland of stored thyroid hormone and prevent radiation thyroiditis, for 5 to 6 weeks prior to the administration of radioactive iodine can be helpful in patients who have significant hyperthyroidism, who are elderly, or who are at risk of decompensation with continued hyperthyroidism (e.g., patients with cardiovascular disease). If given, antithyroid drugs should be discontinued 5 days prior to giving radioiodine so that its uptake will not be impacted.

Surgery

Thyroid surgery is very effective for the treatment of hyperthyroidism, including Graves disease and nodular hyperthyroidism. Complications include damage to the parathyroid glands or the recurrent laryngeal nerve, but these risks are extremely low when the procedure is performed by an experienced surgeon. In preparation for surgery, the patient should first be rendered euthyroid with antithyroid drugs. Patients with Graves disease should also receive potassium iodide or Lugol solution under expert guidance to decrease the vascularity of the gland.

Treatment of Select Hyperthyroid Disorders

Graves Disease

For Graves disease, the most common initial treatment is antithyroid drugs, followed by radioactive iodine, with surgery as the least chosen option.[14] In patients who have Graves ophthalmopathy or very large thyroid glands, antithyroid drugs or surgery is preferred and radioactive iodine is not recommended. The choice among therapies should be patient-centered, but data suggest that long-term quality of life will be equivalent for most patients.

Other Causes of Hyperthyroidism

For toxic multinodular goiters, which often present in elderly patients, a small dose of an antithyroid drug may be effective. For autonomously functioning single nodules, radioactive iodine or thyroid lobectomy is usually preferred.

Subclinical Hyperthyroidism

In subclinical hyperthyroidism, patients have a confirmed suppressed TSH level but normal thyroid hormone levels. The most common cause of this disorder is a toxic multinodular goiter, with autonomous nodules that do not remit; as a result, hyperthyroidism typically will worsen gradually over time if treatment is not instituted. These patients have an increased risk of atrial arrhythmias, heart failure, and bone loss, especially if they are over age 65 years. Patients over age 65 years should be treated chronically with a low dose of methimazole (2.5 to 10 mg), which typically will allow the TSH level to rise into the normal range. If the TSH level is <0.1 mIU/L, patients who are less than age 65 years should be treated if they have a comorbid condition, such as heart disease or osteoporosis, and treatment should be considered even without comorbid conditions or symptoms. If the TSH level is partially suppressed (>0.1 and <0.45), treatment should be considered in all patients who have comorbid conditions.

Hyperthyroidism and Pregnancy

Graves disease affects 1 per 500 pregnancies, usually because it was not adequately treated prior to conception. The differential diagnosis must include gestational thyrotoxicosis secondary to elevated production of human chorionic gonadotropin, generally in the first trimester and especially women with a twin pregnancy or hyperemesis gravidarum. Significant hyperthyroidism during pregnancy can be devastating for fetal survival and maternal health, although both Graves disease and gestational thyrotoxicosis tend to remit or improve starting at the end of the first trimester. Thyrotropin receptor autoantibody levels above the reference range can be the most useful test to establish the diagnosis. For symptomatic control, β-blockers (labetalol is preferred during pregnancy) can be used but only for very short periods of time and at low doses (e.g., 100 mg twice daily). If antithyroid drugs are required, propylthiouracil should be used in the first trimester rather than methimazole, but at the lowest dose needed to control symptoms. Although both antithyroid drugs are associated with a risk of fetal anomalies, propylthiouracil is considered safer than methimazole during the period of organogenesis in the first trimester.[15] The free T_4 level should be maintained at or above the upper level of normal so that the antithyroid drug does not impact the fetal thyroid gland, which is more sensitive to it than is the maternal thyroid gland.

Thyroid Storm or Crescendo Thyrotoxicosis

Thyroid storm refers to systemic destabilization and hemodynamic compromise in the setting of severe thyrotoxicosis. Mortality may approach 30%. Clinical manifestations include hyperthermia, neurologic toxicity with coma or seizures, and cardiac toxicity with arrhythmias, myocardial ischemia, and heart failure. A comorbid condition such as sepsis, an underlying cardiac problem, or unrelated surgery often triggers the decompensation. The most common cause of thyroid storm is Graves disease, but a severely toxic multinodular goiter can precipitate the syndrome. All thyroid hormone levels will be elevated, but the diagnosis is clinical because similarly high values can be seen in patients without thyroid storm. Treatment is focused on decreasing thyroid hormone levels, particularly the T_3 level, as quickly as possible and on identifying and correcting any potential precipitating cause. If high-dose β-blockade can be tolerated hemodynamically, it should be instituted with propranolol (started at 60 to 80 mg orally every 4 to 6 hours and titrated to optimize heart rate and blood pressure); if tolerance is uncertain, intravenous short-acting esmolol (started at 50 to 100 μg/kg/minute) can be used. To lower thyroid hormone levels acutely, propylthiouracil (starting at 200 to 400 mg every 4 to 6 hours) is preferred because, like propranolol and unlike methimazole, it blocks the type 1 deiodinase and prevents conversion of T_4 to T_3. Once propylthiouracil has been started, iodine (e.g., up to 5 drops every 6 hours) can then be added to block the release of thyroid hormone. High-dose glucocorticoids (e.g., 100 mg of hydrocortisone every 8 hours or 4 mg of dexamethasone every 8 to 12 hours) also inhibit the conversion of T_4 to T_3 and should be utilized until severe hyperthyroidism is controlled. In extreme crises, plasmapheresis or emergency thyroidectomy can be performed.

Non-Thyroid Complications of Graves Disease

Unlike other causes of hyperthyroidism, Graves disease presents with immune-related extrathyroidal manifestations unrelated to excess levels of thyroid hormones,[16] including Graves ophthalmopathy and dermopathy. Graves ophthalmopathy is caused when activation of the TSH receptor on orbital fibroblasts leads to the production of glycosaminoglycan and the enlargement of extraocular muscles and retroorbital tissue.

Also known as pretibial myxedema because of the location, Graves dermopathy is associated with very high levels of thyrotropin receptor autoantibodies. Activated dermal fibroblasts that express the TSH receptor are the likely mediators.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

At the time when the diagnosis of Graves disease is first made, about 25% of patients have some form of Graves ophthalmopathy, and another 9% develop it subsequently. Furthermore, about 10% of patients with Graves ophthalmopathy are not biochemically hyperthyroid when diagnosed. Most patients with Graves ophthalmopathy notice initial redness in the eyes or swelling in the eye region, grittiness, and photosensitivity

(see Fig. 207-2). As the disease progresses, the eyelid retracts further and frank exophthalmos develops, with bulging of the corneal edge beyond the epicanthal edge. As severity progresses, involvement of the ocular muscles can cause diplopia and, more rarely, compression of the optic nerve. Clinically, Graves ophthalmopathy is relatively easy to diagnose and can be quantified using a variety of classification scores that measure inflammation and exophthalmos.[17]

All patients with Graves dermopathy have concomitant hyperthyroidism and Graves ophthalmopathy. Graves dermopathy is characterized by nonpitting edema with orange to violet discoloration. In severe cases, overgrowth of plaques and nodules cause a disfiguring lesions.

TREATMENT

Mild Graves ophthalmopathy is usually just observed or potentially treated with selenium (200 μg daily) for at least 6 months. For moderate to severe disease, standard first-line treatment has been intravenous pulse methylprednisolone under expert guidance over a 12-week period.[18] However, teprotumumab (10 mg/kg as an initial single dose, followed by 20 mg/kg every 3 weeks for 7 additional doses), which is a monoclonal antibody that inhibits IGF-1 receptors, can significantly improve exophthalmos and diplopia and is becoming a first-line option.[A5,A6] In patients who do not respond, second-line therapy includes orbital radiation or further immunosuppression with agents such as rituximab under expert supervision. Orbital surgery for ophthalmic nerve decompression is usually reserved for inactive Graves ophthalmopathy to improve function and cosmetic appearance.

For Graves dermopathy, no treatment is usually required. If required, treatment is usually local, with steroid creams (Table 403-10).

THYROIDITIS

Postpartum and Sporadic Painless Thyroiditis

EPIDEMIOLOGY AND PATHOBIOLOGY

Postpartum thyroiditis, which occurs after up to 10% of pregnancies, is more frequent in women with a personal or family history of autoimmunity and in women who have thyroid peroxidase antibodies during the first trimester of pregnancy. In the postpartum setting, the incidence of postpartum thyroiditis is about 20 times higher than that of Graves hyperthyroidism. The incidence of painless thyroiditis outside of the postpartum setting is unknown, but it is less frequent than postpartum thyroiditis. It typically occurs in individuals between ages 30 and 60 years and is 1.5 times more likely to occur in women than in men.

Sporadic painless thyroiditis and postpartum thyroiditis are variants of the same autoimmune disorder, essentially indistinguishable except that postpartum thyroiditis occurs in the first 12 months following delivery. Both are forms of destruction-induced thyroiditis.

CLINICAL MANIFESTATIONS

The classic sequence is a transient thyrotoxicosis due to leakage of preformed hormone from a damaged gland, followed by transient hypothyroidism owing to depleted thyroid hormone stores. However, not all patients experience both phases. About 25% of women with postpartum thyroiditis experience only transient thyrotoxicosis, and about half experience only the hypothyroid phase.

In the initial thyrotoxic phase, symptoms such as tachycardia, palpitations, and heat intolerance may occur, and a nontender goiter is usually present. However, thyroid hormone levels are lower in sporadic painless thyroiditis and postpartum thyroiditis than in Graves disease, so patients tend to be less symptomatic. Features that develop only with longstanding thyrotoxicosis, such as substantial weight loss, are rare. The toxic phase usually persists for 1 to 3 months and may be followed by a brief period of euthyroidism for 1 to 2 months. The final, hypothyroid, phase may persist for up to 1 year. Symptoms in the hypothyroid phase may include fatigue, impaired concentration, constipation, and cold intolerance. Hypothyroidism in patients who initially presented with thyrotoxicosis is often briefer and less severe than when hypothyroidism is the presenting disorder.

DIAGNOSIS

During the toxic phase of painless thyroiditis, release of hormone from the inflamed thyroid results in increases in levels of serum free T_4 and T_3 and a decrease in the serum TSH level. The serum T_3 : T_4 ratio, which is usually <20, reflects the ratio of stored hormone in the thyroid gland and differs from Graves disease, in which T_3 is often preferentially elevated. The thyroid peroxidase antibody is positive in most patients, but thyrotropin receptor autoantibody assays are negative, thereby helping to differentiate this disorder from Graves hyperthyroidism. Stigmata of Graves disease, such as exophthalmos or a thyroid bruit, are absent.

FIGURE 207-5. Goiter.

Although not routinely needed for diagnosis, a low to undetectable radioactive iodine uptake will be seen during the thyrotoxic phase (Fig. 207-5). Thyroid ultrasonography shows a heterogeneous and hypoechoic echotexture; during the toxic phase, color Doppler flow is markedly decreased, compared with the marked increase seen in Graves disease. During recovery from the acute toxic phase, the TSH level increases and the serum TSH level rises, so radioactive iodine uptake and color Doppler flow may be normal or elevated.

In patients in whom the toxic phase either was missed or never occurred, the presentation of hypothyroidism is the same as in other forms of hypothyroidism. The serum TSH level will be elevated, and, depending on the severity of the hypothyroidism, free T_4 levels may be low.

TREATMENT

The clinical course of sporadic painless thyroiditis is self-limited. If signs and symptoms of thyrotoxicosis are moderate or severe, they should be treated symptomatically with β-adrenergic blocking drugs (e.g., atenolol 25 to 50 mg daily) in the ambulatory setting until thyroid hormone levels fall and symptoms resolve. Since the synthesis of thyroid hormone is not increased, antithyroid drugs are not useful. In sporadic painless or postpartum thyroiditis, hypothyroidism requires treatment if symptoms are severe or prolonged. If levothyroxine therapy (weight based if overtly hypothyroid or low dose if subclinically hypothyroid) is initiated, it can be tapered after 6 to 12 months to determine whether the underlying thyroid function has recovered. However, levothyroxine should be continued for the duration of the pregnancy if the patient is pregnant or attempting conception.

PROGNOSIS

Although many patients return to a euthyroid state, up to 50% remain chronically hypothyroid. Permanent hypothyroidism is more frequent in the setting of high titers of thyroid peroxidase antibodies, when a thyrotoxic phase was not detected, and when hypothyroidism is more severe. Postpartum thyroiditis recurs after 70% of subsequent pregnancies.

Subacute (de Quervain) Thyroiditis

DEFINITION

Subacute thyroiditis, which is the most common cause of a painful thyroid gland, is an inflammatory disorder of unknown cause.

EPIDEMIOLOGY AND PATHOBIOLOGY

Subacute thyroiditis, which accounts for up to 5% of clinical thyroid disorders, is five times more frequent in women than in men, with a peak incidence in the fourth and fifth decades. Subacute thyroiditis often follows a viral

prodrome and occurs seasonally, coinciding with the peak in enterovirus infections. It also has been reported to follow infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).[19] The initial thyrotoxic phase is caused by leakage of preformed thyroid hormone from the damaged thyroid gland into the circulation, typically persisting for 2 to 4 months. In about one-third of patients, the initial phase is followed by a subsequent hypothyroid phase during which stored intrathyroidal hormone is depleted, but the gland has not recovered sufficiently to resume normal synthesis of thyroid hormone.

CLINICAL MANIFESTATIONS

Subacute thyroiditis often develops 2 to 3 weeks after an upper respiratory tract or other viral infection. The onset of thyroid pain or swelling may be accompanied by fever and other systemic symptoms, such as myalgias and fatigue. About 50% of patients will have thyrotoxic symptoms. Pain and tenderness are moderate to severe and may radiate to the angle of the jaw, to the ear, or to the anterior chest. Both thyroid lobes may be simultaneously involved, or pain may start on one side and migrate to the other. The thyroid is generally firm and exquisitely tender to palpation over one or both lobes. Cervical lymphadenopathy is absent.

DIAGNOSIS

Subacute thyroiditis must be differentiated from other causes of anterior neck pain, including acute hemorrhage into a nodule or cyst, infectious thyroiditis, and (rarely) rapidly enlarging thyroid carcinoma. During the painful phase, the hallmark of subacute thyroiditis is an elevated erythrocyte sedimentation rate (ESR). The white blood cell count is normal or mildly increased. The serum TSH level will be low or undetectable during the thyrotoxic phase, with a serum T_4 to serum T_3 ratio >20:1 reflecting the intrathyroidal stores of each hormone. Serum levels of thyroid peroxidase and thyroglobulin antibody are usually normal. Although the diagnosis can usually be made without imaging, radioactive iodine uptake during the thyrotoxic phase is low to undetectable and can be used diagnostically. If utilized, ultrasound examination may show generalized, multiple, or single regions of hypoechogenicity.

TREATMENT AND PROGNOSIS

Thyrotoxic symptoms are usually mild and can be managed with β-adrenergic blocking drugs (e.g., atenolol 25 to 50 mg daily) until thyroid hormone levels fall and symptoms resolve. Antithyroid drugs are not indicated. Nonsteroidal anti-inflammatory drugs can be used to manage mild to moderate thyroid pain. In more severe cases, oral glucocorticoids (e.g., prednisone 40 to 60 mg a day) may be helpful, with a slow taper over at least 4 to 6 weeks to reduce the likelihood that symptoms will recur.

The acute phase may be followed by a period of transient (1 to 2 months) asymptomatic euthyroidism. Hypothyroidism, persisting for up to 6 to 9 months, may be the final phase before recovery and may require levothyroxine therapy (weight based if overtly hypothyroid or low dose if subclinically hypothyroid) if symptomatic.

Infectious Thyroiditis

DEFINITION

Infectious thyroiditis, which is also known as acute or suppurative thyroiditis,[20] is usually caused by bacteria, but fungal and parasitic thyroiditis have also been reported.

EPIDEMIOLOGY AND PATHOBIOLOGY

Infectious thyroiditis, which is rare, represents <1% of all thyroid disease. The thyroid gland's high iodine content, vascularity, lymphatic drainage, and protective capsule make it resistant to infection. *Staphylococcus aureus* and *Streptococcus pyogenes* are the pathogens in about 40% of adults, whereas α- and β-hemolytic streptococcus and a variety of anaerobic organisms account for most cases in children. The presence of anatomic variations such as pyriform sinus fistulae may predispose to the development of thyroid infection. Immunosuppressed patients, particularly from HIV infection, are also at increased risk.

CLINICAL MANIFESTATIONS

Patients typically present with thyroid pain, tenderness, and local compression that result in dysphagia and dysphonia. Systemic symptoms such as fever, chills, tachycardia, and malaise may also be noted. The presentation may be more insidious in fungal than in bacterial infections.

DIAGNOSIS

Infectious thyroiditis may be difficult to differentiate from subacute thyroiditis in the early phases, although patients with bacterial thyroiditis tend to have a higher fever and are much less likely to have clinically overt thyroid dysfunction. The white blood cell count can be elevated in both conditions. Once abscess formation has occurred, local erythema, lymphadenopathy, hyperpyrexia, and leukocytosis should lead to the correct diagnosis. Thyroid function tests are most frequently normal, but hypothyroidism and thyrotoxicosis have been reported. Affected thyroid regions are hypoechoic on ultrasound and cold on scintigraphy. Diagnosis can be made by fine-needle aspiration with Gram stain and culture.

TREATMENT AND PROGNOSIS

The infectious microorganism should be identified from needle aspirate, from incision and drainage, or from blood culture. If no organisms are seen on the Gram stain, empiric treatment with nafcillin and gentamicin or with a third-generation cephalosporin under expert supervision is appropriate initial therapy in adults. If the patient does not respond promptly or if an abscess develops, incision and drainage is necessary. In some cases, especially if the disease is recurrent, partial lobectomy is required. Mortality is rare with appropriate treatment, and recurrence is unlikely.

Drug-Induced Thyroiditis

Amiodarone, lithium, interferon-α, multikinase inhibitors, and immune checkpoint inhibitors may cause painless thyroiditis.[21] Cytokine therapy, specifically interferon-α, also can cause a painless destructive thyroiditis in addition to other forms of thyroid dysfunction.

Amiodarone

Amiodarone, because of its high iodine content, is a frequent mediator of thyroid dysfunction. Most commonly it causes hypothyroidism especially in patients who have an underlying autoimmune thyroid disease. Unfortunately, amiodarone can also lead to hyperthyroidism in a small percentage of patients treated. Amiodarone causes hyperthyroidism through two pathways; type 1 is called iodine-induced thyrotoxicosis and is more common in patients who have underlying nodular thyroid disease; type 2 is a painless thyroiditis due to the drug. Often it is difficult to distinguish between the two clinically.

Lithium

Treatment with lithium can lead to endocrine complications including primary hyperparathyroidism, nephrogenic diabetes insipidus, and hypothyroidism. The mechanism by which lithium leads to hypothyroidism is not clear, but it can be easily treated with L-thyroxine.

Kinase Inhibitors, Interferon Therapy, and Immune Checkpoint Inhibitors

Each of these therapies can lead to a painless thyroiditis that most commonly presents with hypothyroidism but can also present with a hyperthyroid phase. Even a single dose of an immune checkpoint inhibitor can cause hypothyroidism or hyperthyroidism due to autoimmune thyroid disease. Additionally, but more rarely, immune checkpoint inhibitors can lead to pituitary dysfunction with central hypothyroidism that presents with low TSH and low thyroid hormone levels.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The key in all cases is to suspect drug-induced thyroid dysfunction. The diagnosis is usually heralded by symptoms of hypothyroidism or hyperthyroidism and can be confirmed by thyroid function testing. In amiodarone-induced thyrotoxicosis, a thyroid ultrasound with Doppler showing blood flow to the gland suggests type 1 rather than type 2 amiodarone-induced thyrotoxicosis.

TREATMENT

In the painless thyroiditis caused by immune checkpoint inhibitors and other immune modifiers, treatment depends upon the phase in which the patient presents. If the patient is hyperthyroid, treatment generally focuses on blocking the hyperadrenergic symptoms with atenolol (25 to 50 mg daily) until thyroid function tests and symptoms improve, usually over 4 to 6 weeks. If the hyperthyroidism does not remit, Graves disease can be considered. The hypothyroid phase of drug-induced thyroid dysfunction tends to be permanent and generally requires L-thyroxine therapy using a weight-based approach (1.6 ug/kg/day).

Of all the drug-induced thyroid disorders, amiodarone-induced hyperthyroidism is the most difficult to treat. If type 1 disease cannot be distinguished from type 2 disease, both should be treated simultaneously using methimazole for type 1 disease and prednisone for type 2 disease. If the hyperthyroidism is moderate, a reasonable starting dose is 10 mg twice a day of each, with close follow-up of thyroid hormone levels. If the hyperthyroidism is significant or severe, higher doses of both drugs may be necessary. Most commonly the amiodarone is also stopped, but its tissue half-life is so long that its discontinuation does not effectively treat the thyrotoxicosis. If a patient has significant cardiac complications from hyperthyroidism and the disease is resistant to medical therapy, a thyroidectomy can emergently treat the hyperthyroidism.

PROGNOSIS

The prognosis of most drug-induced thyroiditis is usually good, but they can progress to permanent hypothyroidism. However, amiodarone-induced thyrotoxicosis can be difficult to treat because of the underlying cardiovascular disease and rarely may require removal of the thyroid gland.

Sclerosing (Reidel) Thyroiditis

Sclerosing thyroiditis, which is a rare disorder of unknown cause, is characterized by dense fibrous tissue that replaces the normal thyroid parenchyma and may extend into adjacent muscle, parathyroid glands, blood vessels, and nerves.[22] It is sometimes associated with IgG4-related systemic disease, which can include fibrosis of the salivary or lachrymal glands or of the peritoneum, and it can also be associated with sclerosing cholangitis, orbital pseudotumor, or fibrosing mediastinitis.

The peak age of onset is in the fourth to sixth decades, and sclerosing thyroiditis is about four times more frequent in women than in men. This condition accounts for about 1 in 100,000 thyroid surgeries.

CLINICAL MANIFESTATIONS

Patients present with rapidly enlarging, painless goiter and often report a sensation of pressure in the anterior neck, difficulty swallowing, or progressive dyspnea. Hoarseness may occur if the recurrent laryngeal nerve is involved. If the fibrotic process affects the entire gland, patients may have symptoms of hypothyroidism. On examination, the thyroid gland is rock hard, usually nontender, and moves poorly on swallowing.

DIAGNOSIS

Most patients with Riedel thyroiditis are initially euthyroid, but some patients develop hypothyroidism. Most patients have detectable thyroid peroxidase antibodies, and some have concurrent hypoparathyroidism. On ultrasound, affected areas are hypoechoic and have absent vascularity. The local extent of the fibrosis can be determined by CT or MRI scanning. An ^{18}FDG-PET scan will show intense uptake in areas of fibrotic inflammation and can assess the possible presence of extrathyroidal disease. The definitive diagnosis is made by biopsy, and open biopsy is often required because the texture of the gland makes fine needle aspiration biopsy difficult.

TREATMENT

Surgery, with total or subtotal thyroidectomy depending on extent of disease, is usually required to relieve compressive symptoms. Thyroid hormone treatment is indicated if hypothyroidism is present. Limited evidence suggests possible benefit from glucocorticoid therapy, tamoxifen, or rituximab to improve symptoms or prevent extrathyroidal disease.

GOITER

Goiter is defined as thyroid enlargement. Goiters are usually diffuse in Graves disease or congenital defects in thyroid hormone synthesis. By comparison, goiters are nodular in the setting of a single nodule or a multinodular goiter. Rarely, thyroid enlargement can appear rapidly, usually in the setting of a poorly differentiated or anaplastic thyroid carcinoma or thyroid lymphoma. Large goiters may not come to medical attention earlier because they do not substantially alter thyroid hormone production and instead may become problematic because of their size. With significant enlargement, goiters can cause tracheal obstruction or a superior vena cava syndrome (see Fig. 86-8). Large nodular goiters can involve the mediastinum and are a cause of an anterior mediastinal mass (Chapter 86).

DIAGNOSIS

A goiter must be carefully evaluated by physical examination and diagnostic testing of thyroid function (see Figs. 207-1 and 207-3). The clinical effects of large goiters can be assessed on a careful physical examination. The Pemberton sign is noted when raising both arms above the head obstructs venous return and leads to facial plethora and redness. Tracheal compromise can be discerned by an airway flow-volume loop looking for external compression (Chapter 73), but the most sensitive technique is a noncontrast CT scan (to prevent an iodine load, which can precipitate acute hyperthyroidism) in the setting of Graves disease or toxic nodular goiter. Diffuse goiters are almost always benign, whereas asymmetric goiters can represent multinodular disease or malignancy.

TREATMENT

Treatment should focus on the underlying cause of the goiter. Large goiters can be treated with total or subtotal thyroidectomy.

THYROID NODULES

Thyroid nodules are noted in up to 60% of adults when the thyroid gland is assessed ultrasonographically, but most such nodules are not clinically significant.[23] Thyroid nodules are more frequent in individuals from iodine-deficient regions, are more common in women than in men, and their frequency increases with age. The vast majority, about 95%, are benign. The likelihood of malignancy is increased in individuals who have a history of radiation treatment to the head or neck during childhood, exposure to ionizing radiation in childhood (e.g., from close proximity to a nuclear accident), or a family history of thyroid cancer. Familial syndromes associated with increased risk for thyroid cancer include Cowden disease, familial adenomatous polyposis (Chapter 179), Carney complex (Table 212-1), and multiple endocrine neoplasia type 2 (Chapter 212).

CLINICAL MANIFESTATIONS

Patients may present with a visible or palpable mass, or nodules may be found incidentally on imaging studies such as carotid ultrasound, CT, MRI, or ^{18}FDG-PET scans. Most nodules are asymptomatic, but large nodules may cause compressive symptoms including cough, dyspnea, hoarseness (due to vocal cord paralysis), dysphagia, or a pressure sensation in the anterior neck. A history of very rapid growth suggests hemorrhage into a benign nodule, anaplastic carcinoma, or thyroid lymphoma. Patients who have autonomously functioning nodules may present with symptoms of hyperthyroidism.

DIAGNOSIS

Clinical assessment of nodules aims to determine whether treatment is needed for symptoms or malignancy and to avoid the overdiagnosis of low-risk thyroid cancers. A physical examination should include palpation to assess the size and location of the nodule(s) as well as to determine whether the nodules are fixed to other structures (suggestive of malignancy) or mobile. Enlarged and firm ipsilateral cervical lymph nodes can be a sign of local tumor metastases.

The serum TSH should be assessed in all patients who have a thyroid nodule measuring at least 1 cm to help determine whether the nodule(s) may be hyperfunctioning (Fig. 207-6). When nodularity is present in the setting of a low serum TSH level, a radioactive iodine scan is needed to establish the diagnosis of nodular autonomy. The serum calcitonin level should be measured if there is clinical suspicion for medullary thyroid cancer, such as in patients with a family history of medullary cancer or multiple endocrine neoplasia type 2.[24]

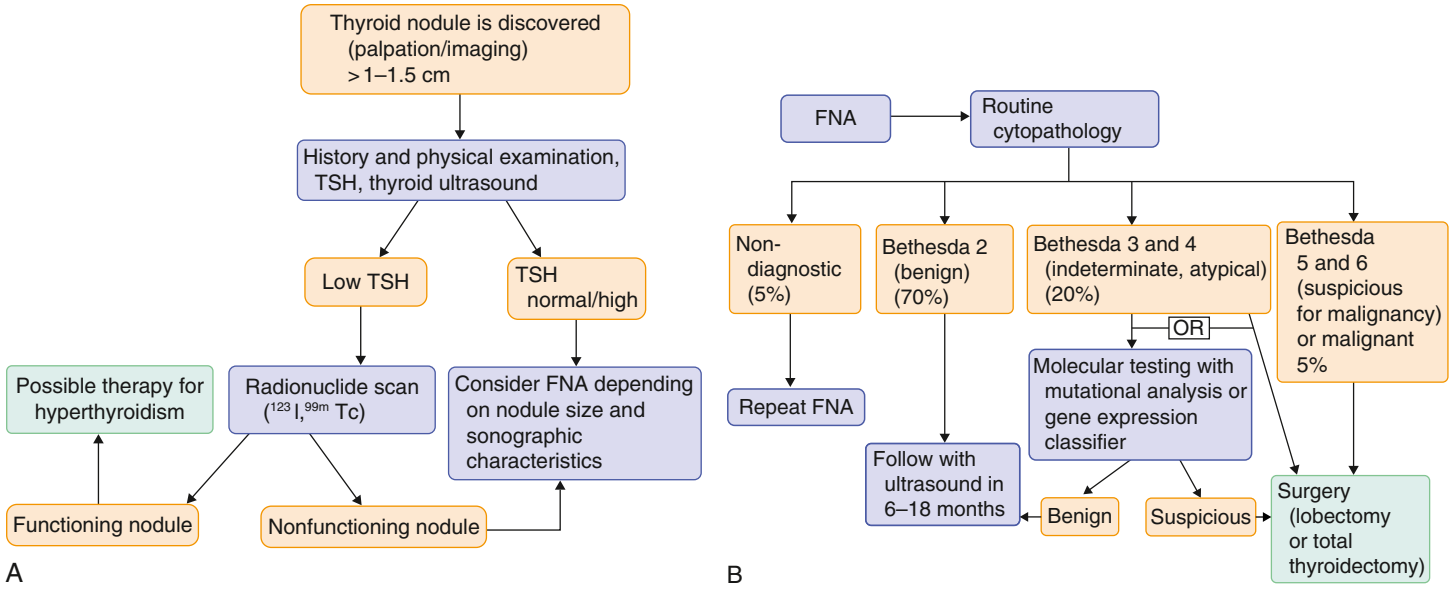

FIGURE 207-6. **A, Initial evaluation of a thyroid nodule. ^{123}I = radioactive iodine 123; ^{99m}Tc = technetium 99m; TSH = thyroid-stimulating hormone. B, Algorithm for evaluation of a thyroid nodule with fine-needle aspiration (FNA). With indeterminate nodules (Bethesda class 3 and 4), surgery, typically a diagnostic lobectomy, or molecular testing are both potential strategies. (From Jonklaas J, Cooper DS. Thyroid. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:1462-1476.)**

TABLE 207-7 AMERICAN THYROID ASSOCIATION SIZE THRESHOLDS FOR THYROID NODULE FINE-NEEDLE ASPIRATION (FNA) BIOPSY BASED ON SONOGRAPHIC RISK STRATIFICATION

NODULE SONOGRAPHIC FEATURES	LIKELIHOOD OF MALIGNANCY	RECOMMENDED NODULE THRESHOLD FOR FNA
AMERICAN THYROID ASSOCIATION		
High suspicion (hypoechoic AND macrocalcifications, taller than wide configuration, irregular borders)	70-90%	≥1 cm
Intermediate suspicion (hypoechoic without suspicious features)	10-20%	≥1 cm
Low suspicion (iso- or hyperechoic without suspicious features)	5-10%	≥1.5 cm
Very low suspicion (spongiform or partially cystic without suspicious features)	<3%	>2 cm or consider not performing biopsy
Benign (simple cyst)	0	No biopsy

The American Thyroid Association system is based on ultrasonographic patterns, unlike the American College of Radiology Thyroid Imaging, Reporting, and Data System (E-Fig. 207-4), which is based on a point system.

Data from Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: The American Thyroid Association Guidelines Task Force on Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid*. 2016;26:1-133.

Imaging

Ultrasonography is the best modality for assessing a thyroid nodule's size, location, echogenicity (cystic, solid, or mixed), shape, margins, calcifications, or other hyperechoic foci, as well as the presence of cervical lymph nodes that might be suspicious for metastatic disease. In patients who have thyroid nodularity and low serum TSH values, thyroid scintigraphy can determine whether nodules are nonfunctioning ("cold"), isofunctioning, or hyperfunctioning (autonomous, or "hot").[25] Autonomously functioning nodules do not require biopsy because the risk of malignancy is very low. However, hypo- and isofunctional nodules warrant biopsy if they otherwise meet criteria.

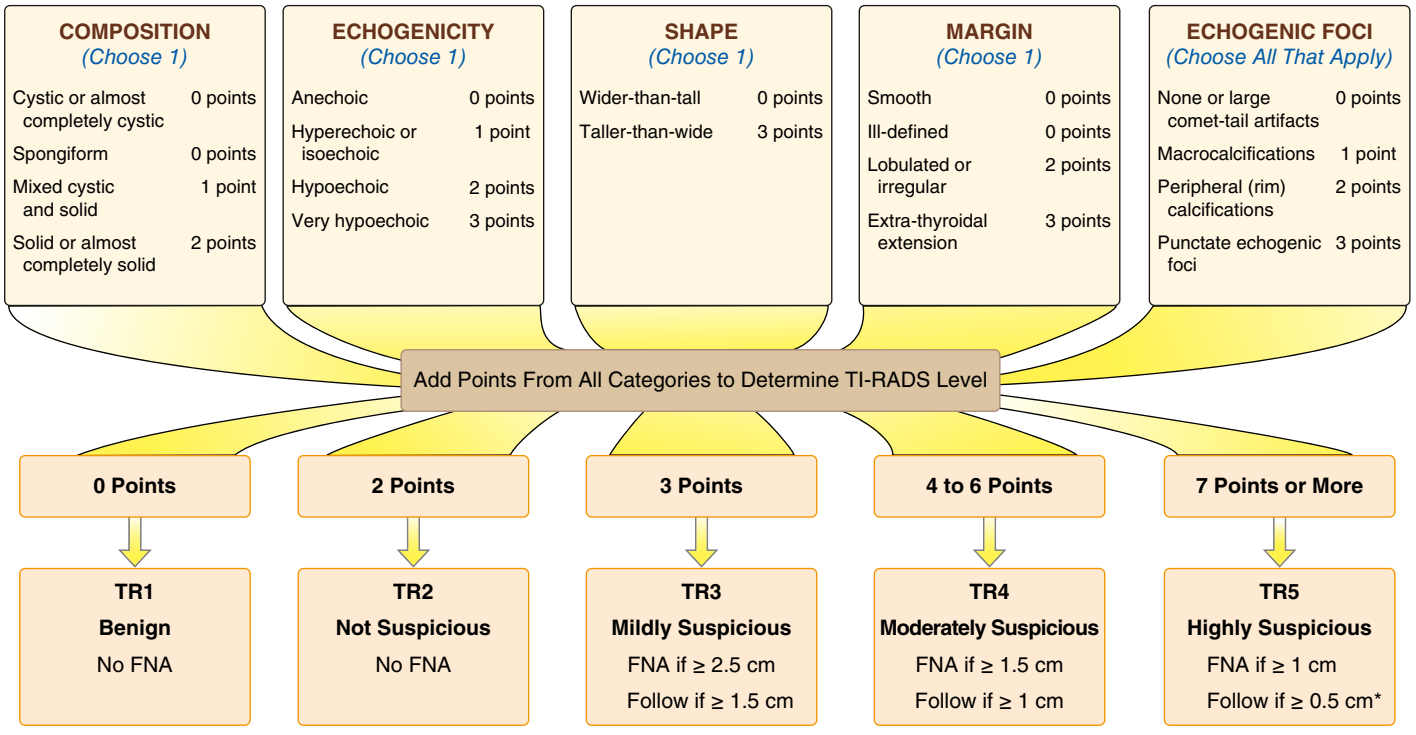
Fine-Needle Aspiration Biopsy

Based on sonographic features, the size of the nodule, and the clinical history, the probability of an underlying malignancy can guide the decision as to whether to perform a fine-needle aspiration biopsy (Table 207-7). In general, nodules <1 cm, cystic nodules, and partially cystic nodules with a spongiform appearance are likely to be benign. Concerning features include hypoechogenicity, irregular margins, being taller than wide when comparing the anteroposterior to the horizontal diameter in the transverse view, extrathyroidal extension, and the presence of microcalcifications or interrupted peripheral macrocalcifications. Additional considerations that may influence the decision about biopsy include the presence of high-risk features such as a family history of thyroid cancer, a history of childhood exposure to head or neck radiation, or comorbid conditions that might preclude thyroid surgery. ^{18}FDG-PET scanning is not recommended as part of the routine evaluation of thyroid nodules, but nodules that are known to be hypermetabolic on ^{18}FDG-PET scanning have about a 35% likelihood of malignancy and should be biopsied if ≥1 cm.

The risk of malignancy is the same when multiple nodules are present as for single nodules, and the risk of each individual nodule must be separately assessed. When multiple nodules with similar features are present, it is reasonable to biopsy the largest and observe the others.

Thyroid nodule cytopathology can usually establish the diagnosis.[26] For the approximately 2 to 16% of nodules that are reported as nondiagnostic, the fine-needle aspiration biopsy should be repeated; if it is again nondiagnostic, thyroid lobectomy can be considered. Nodules that are classified as malignant (Bethesda class VI) have a 98% probability of being papillary thyroid carcinoma. For the 20% or so of nodules that are classified as atypia of undetermined significance or as follicular neoplasm, the likelihood of malignancy ranges from about 10 to 40%; for these indeterminate nodules, options under expert supervision include repeat fine-needle aspiration biopsy, which may yield diagnostic results, diagnostic lobectomy, or molecular markers to refine the estimates of malignancy.[27]

AMERICAN COLLEGE OF RADIOLOGY THYROID IMAGING, REPORTING, AND DATA SYSTEM



COMPOSITION	ECHOGENICITY	SHAPE	MARGIN	ECHOGENIC FOCI
Spongiform: Composed predominantly (>50%) of small cystic spaces. Do not add further points for other categories. *Mixed cystic and solid:* Assign points for predominant solid component. Assign 2 points if composition cannot be determined because of calcification.	*Anechoic:* Applies to cystic or almost completely cystic nodules. *Hyperechoic/isoechoic/hypoechoic:* Compared with adjacent parenchyma. *Very hypoechoic:* More hypoechoic than strap muscles. Assign 1 point if echogenicity cannot be determined.	*Taller-than-wide:* Should be assessed on a transverse image with measurements parallel to sound beam for height and perpendicular to sound beam for width. This can usually be assessed by visual inspection.	*Lobulated:* Protrusions into adjacent tissue. *Irregular:* Jagged, spiculated, or sharp angles. *Extrathyroidal extension:* Obvious invasion = malignancy. Assign 0 points if margin cannot be determined.	*Large comet-tail artifacts:* V-shaped, >1 mm, in cystic components. *Macrocalcifications:* Cause acoustic shadowing. *Peripheral:* Complete or incomplete along margin. *Punctate echogenic foci:* May have small comet-tail artifacts.

FNA = fine needle aspiration. (From Tessler FN, Middleton WD, Grant EG, et al. ACR Thyroid Imaging, Reporting and Data System [TI-RADS]: white paper of the ACR TI-RADS Committee. *J Am Coll Radiol*. 2017;14:587-595.)

TABLE 207-8 RISK FOR PERSISTENCE/RECURRENCE IN DIFFERENTIATED THYROID CANCER

CANCER TYPE	RECURRENCE RISK	CHARACTERISTICS
Papillary	**Low**	All of the following: • No local or distant metastases • All macroscopic tumor has been resected • No tumor invasion of loco-regional tissues or structures • The tumor does not have aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) • No vascular invasion • ≤5 pathologic cervical nodal micrometastases (<0.2 cm in largest dimension) Intrathyroidal microcarcinoma (<1 cm), unifocal or multifocal
	Intermediate	Microscopic invasion into perithyroidal soft tissues Radioactive iodine-avid metastatic foci in the neck on the first posttreatment whole-body ^{131}I scan Aggressive histology (e.g., tall cell, hobnail variant, columnar cell carcinoma) Vascular invasion >5 pathologic cervical nodal metastases with all involved lymph nodes <3 cm in largest dimension Multifocal microcarcinoma (<1 cm), with extrathyroidal extension
	High	Macroscopic invasion of tumor into perithyroidal soft tissues Incomplete tumor resection Distant metastases or postoperative serum thyroglobulin suggestive of distant metastases Cervical node metastases with any metastatic lymph node ≥3 cm in largest dimension
Follicular	**Low**	Intrathyroidal, well differentiated thyroid cancer with capsular invasion and no or minimal (<4 foci) vascular invasion
	High	>4 foci of vascular invasion

Adapted from Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association management guidelines for adult patients with thyroid nodules and differentiated thyroid cancer: the American Thyroid Association Guidelines Task Force on Thyroid Nodules and Differentiated Thyroid Cancer. *Thyroid*. 2016;26:1-133.

TREATMENT

Nodules that are cytologically benign or are too low risk to require biopsy can be followed with periodic ultrasonography. For nodules with high-risk features but benign cytology, repeat fine-needle aspiration may be considered within 12 months. Repeat fine-needle aspiration is also recommended for cytologically benign nodules that grow >20% in diameter or >50% in volume over the course of follow-up. Premalignant lesions, known as noninvasive follicular thyroid neoplasm with papillary-like nuclear features, require surgical resection for diagnosis. Radiofrequency ablation is now becoming an alternative option for reducing the size of benign nodules at many centers.[28] Surgery may be indicated for relief of compressive symptoms or for definitive diagnosis of nodules with suspicious cytopathology. Decisions about the extent of surgery (thyroid lobectomy or total thyroidectomy) depend on whether nodularity is bilateral and on the likelihood of malignancy. Lobectomy is generally preferred when surgery is elected for nodules with indeterminate cytopathology.

Aspiration may reduce the size of simple cysts that cause compressive symptoms or discomfort. Percutaneous ethanol injection can reduce the volume of thyroid cysts that recur following aspiration. Minimally invasive microwave, laser, or radiofrequency ablation are promising alternatives to reduce the size of solid or complex benign nodules.

THYROID CANCER

Thyroid cancers can be of multiple cell types. By far the most common are papillary carcinomas followed by follicular tumors. Medullary thyroid cancer, anaplastic thyroid cancer, and lymphomas of the thyroid are much less common.

Papillary and Follicular (Differentiated) Thyroid Cancer

EPIDEMIOLOGY

Papillary and follicular thyroid cancers occur in all age groups, with a mean age at diagnosis of 48 years. Thyroid cancer is three times more frequent in women than in men. The incidence of thyroid cancer increased about threefold in the United States starting in the 1970s, to a peak of about 14 cases per 100,000 by 2011 to 2016, but rates have started to decline in the past 5 years.[29] Despite the increased incidence, thyroid cancer–specific mortality has remained stable to modestly increased, with 5-year survival rates of >98%. These data suggest that the changes in incidence may have been more related to temporal trends in diagnostic vigor than to a true change in incidence.

PATHOBIOLOGY

Papillary and follicular tumors, which are derived from thyroid follicular epithelial cells, comprise the vast majority of thyroid malignancies (70 to 80% papillary, 10 to 15% follicular). Most papillary cancers are caused by either *BRAF* V600E or *RAS* mutations, and most follicular cancers are caused by mutations either of *RAS* or of the *PAX8-PPARγ* fusion oncogene. Although papillary and follicular carcinomas have differing underlying biology, their diagnosis and treatment are similar. Hürthle-cell carcinoma, which is a variant of follicular thyroid carcinoma, tends to be refractory to radioactive iodine.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Papillary and follicular thyroid cancers most frequently present as a thyroid nodule, either on palpation or as an incidental finding on imaging. Rarely, patients may present with symptoms of metastatic disease. Routine population screening for thyroid cancer using palpation or ultrasound is not recommended and may lead to the overdiagnosis of low-risk tumors. However, screening may be appropriate in high-risk asymptomatic individuals with a history of childhood exposure to ionizing radiation or with familial disorders linked to an increased risk of thyroid cancer (Chapter 212).

Diagnosis is as for a thyroid nodule (see above).

TREATMENT

Patients with small, low-risk tumors (solitary papillary tumors <1 cm in size and without high-risk ultrasonographic features) may elect a strategy of active surveillance rather than immediate surgery.[30] Such patients are followed with serial ultrasound examinations, and surgery is performed if the nodule grows or local lymph node metastases develop.

Primary Surgical Treatment

Otherwise, the primary treatment for thyroid cancers is surgical, preferably guided by preoperative ultrasound and performed by a high-volume thyroid surgeon to reduce the likelihood of damage to the parathyroid glands or recurrent laryngeal nerve.[31] In experienced centers, ambulatory thyroidectomy is a safe and efficacious outpatient surgery.[A7] Total thyroidectomy, which is required prior to treatment with radioactive iodine, is preferred if the primary tumor is ≥4 cm, if the tumor extends beyond the thyroid gland, or in the presence of clinically apparent involved lymph node or distant metastases. For tumors 1 to 4 cm in size without extrathyroidal extension, either lobectomy or total thyroidectomy can be elected.[32]

Postoperative Radioactive Iodine

Radioactive iodine treatment after thyroidectomy confers a survival benefit for high-risk tumors, may be considered for intermediate-risk tumors, but is of no prognostic benefit for low-risk tumors (Table 207-8).[A8] However, radioactive iodine (I-131) may be used to ablate residual normal thyroid tissue (to facilitate surveillance with serum Tg or radioactive iodine whole-body scanning) or to provide adjuvant therapy for subclinical micrometastases or clinically apparent residual or metastatic tumor. Prior to treatment, patients are given TSH or should have their thyroid hormone replacement withheld for 2 to 4 weeks to maximize uptake of the iodine.

Postoperative Thyroid Hormone Treatment

All patients who undergo total thyroidectomy and up to 66% of patients who undergo thyroid lobectomy will require thyroid hormone replacement. In patients at high risk for recurrent tumor, TSH-suppressive levothyroxine to maintain a serum TSH level of <0.1 mIU/L decreases tumor-specific mortality. In intermediate-risk tumors, the initial goal is more modest TSH suppression, with

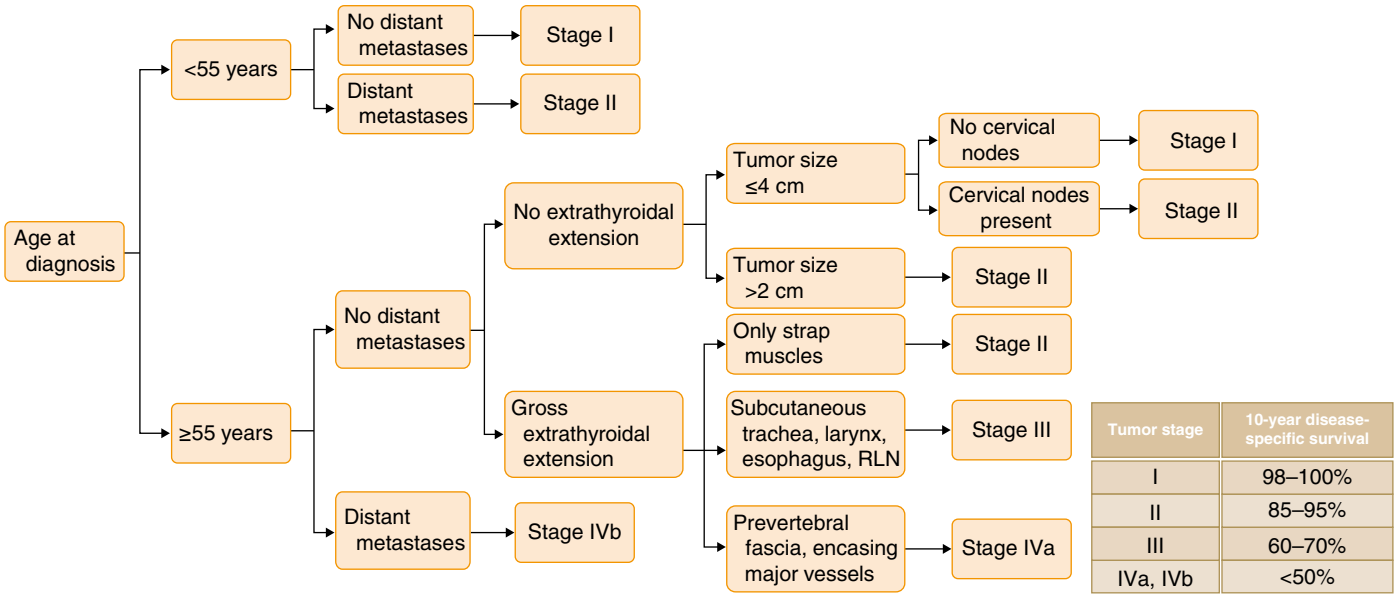


FIGURE 207-7. Prognosis of differentiated thyroid cancer. RNL = recurrent laryngeal nerve. (Data from *American Joint Committee on Cancer. AJCC Cancer Staging Manual*, 8th ed. New York: Springer International Publishing; 2017.)

a target TSH level of 0.1 to 0.5 mIU/L. Patients who are at low risk for recurrence do not benefit from TSH-suppressive levothyroxine dosing; the target in this group is in the low-normal range, or 0.5-2.0 mIU/L. TSH goals may need to be modified in patients who have an increased risk of adverse consequences from iatrogenic thyrotoxicosis, including patients who are older, have cardiovascular risk factors, or who have osteoporosis.

Recurrent or Persistent Disease

For patients with persistent or recurrent disease, central and/or lateral neck dissection may be used for locoregional extension. Repeated radioactive iodine treatment can be helpful for nonresectable locoregional recurrences or distant metastases that are radioactive iodine avid on scanning. External beam radiation therapy is occasionally used for skeletal or brain metastases.

Differentiated thyroid cancers are poorly responsive to conventional chemotherapy. The multikinase inhibitors sorafenib (400 mg twice daily) and lenvatinib (24 mg daily) are FDA-approved for the treatment of advanced differentiated thyroid cancers.[A9] Multikinase inhibitors have multiple adverse effects, including hypertension, renal toxicity, arthralgia, headache, hand-foot skin reaction, diarrhea, and muscle wasting. Larotrectinib (100 mg twice daily) and entrectinib (600 mg daily) are selective inhibitors that are FDA-approved for solid tumors with an *NTRK* fusion.[A10] Pralsetinib (400 mg daily) and selpercatinib (120 to 160 mg twice daily) are selective inhibitors that are FDA approved for *RET*-altered thyroid cancer. When possible, systemic agents should be administered in the setting of a clinical trial. The tumor's specific mutations or signaling pathway abnormalities should inform the selection of the systemic therapy drug.

Follow-Up

The serum thyroglobulin level is a sensitive tumor marker in patients who have undergone total thyroidectomy for differentiated thyroid cancer. During the initial period of follow-up, the serum thyroglobulin level should be measured at least every 6 to 12 months. Approximately 15% of the adult population has autoantibodies directed against thyroglobulin; in these individuals, serum thyroglobulin levels are unreliable, but changes in the thyroglobulin antibody titers can be used as a surrogate tumor marker.

Because the majority of persistent or recurrent papillary thyroid cancer will present in the thyroid bed or as cervical nodal metastases, neck ultrasonography is a mainstay of tumor surveillance. Neck ultrasound is initially recommended at 6 to 12 months postoperatively, with the subsequent frequency and duration of ultrasonographic surveillance dictated by the patient's risk and response to therapy.

In patients who have elevated serum thyroglobulin levels or in whom persistent or recurrent disease is suspected, whole-body radioactive iodine scanning may be helpful after thyroidectomy or radioactive iodine treatment to determine the presence of nodal or distant metastases. Scanning may be repeated at 6 to 12 months to ensure that areas of prior uptake have been ablated. Chest CT scans may be helpful to detect disease in the retropharyngeal nodes and in the mediastinum, hilum, and lungs in patients who have thyroglobulin levels >10 ng/mL but normal neck ultrasound findings ^{18}FDG-PET scanning should be considered in high-risk patients with elevated serum Tg (>10 ng/mL) when radioactive iodine imaging is negative.

PROGNOSIS

Following surgery, prognosis is based on the patient's age, the size of the tumor, the presence and extent of extrathyroidal extension, and the presence of metastases (Fig. 207-7). For the vast majority of patients with differentiated thyroid cancers, however, the risk of dying from the thyroid cancer still is low. Follicular cancers that are intrathyroidal, well differentiated, and with no or minimal (<4 foci) vascular invasion are considered low risk for recurrence, whereas tumors with more foci of vascular invasion are considered high risk. Intrathyroidal papillary carcinomas are at low risk for recurrence if there is no evidence of extrathyroidal extension, vascular invasion, or distant metastases, with or without up to five local lymph node micrometastases (<0.2 cm in largest dimension). Intermediate-risk papillary carcinomas may have microscopic extrathyroidal extension, more than five cervical lymph node metastases if all are less than 3 cm in size, vascular invasion, or aggressive tumor histology. High-risk papillary carcinomas are tumors that were incompletely resected or associated with gross extrathyroidal extension, any metastatic lymph node ≥3 cm in the largest dimension, distant metastases, or high postoperative serum thyroglobulin values suggesting the presence of distant metastases.

The initial postoperative risk stratification should be modified over time to incorporate the patient's response to therapy (Table 207-8). In patients who have had an excellent response to therapy (defined as the absence of clinical, biochemical, or structural evidence of disease: a serum Tg on levothyroxine of <0.2 mg/mL with negative neck ultrasound), the likelihood of recurrent tumor in these patients is very low, and both the degree of TSH suppression and the intensity of tumor surveillance can be relaxed. A structural incomplete response to therapy, which confers high risk, is defined as the presence of loco-regional or distant metastases on imaging. Most of these patients will have persistent disease, and patients with distant metastases have a tumor-specific mortality of up to 50%.

Medullary Thyroid Cancer

Medullary thyroid cancer is a neuroendocrine tumor of the thyroid parafollicular C cells.[33] The primary oncogene is *RET*, which encodes a tyrosine kinase receptor. Medullary thyroid cancer is rare, comprising just 1 to 2% of thyroid cancers in the United States. About 75% of medullary cancer cases are sporadic, with the remainder occurring as a manifestation of the autosomal dominant multiple endocrine adenomatosis type 2A or multiple endocrine adenomatosis type 2B syndromes (Chapter 212). All patients with multiple endocrine adenomatosis type 2A will eventually develop medullary thyroid cancer, most frequently in the third decade of life, and some also develop pheochromocytomas (Chapter 209), Hirschsprung disease (Chapter 122), and/or primary hyperparathyroidism (Chapter 227). In patients with multiple endocrine adenomatosis type 2B, medullary

thyroid cancer is highly aggressive and often presents in infancy; about 50% of affected patients will develop pheochromocytomas, and other manifestations include a marfanoid habitus, mucosal neuromas, and intestinal ganglioneuromas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most sporadic medullary thyroid cancers are diagnosed in patients ages 40 to 70 years. The typical presentation is with a solitary thyroid nodule. Most patients have cervical node metastases at the time of diagnosis, and distant metastases are present in 10%. Diarrhea and facial flushing may occur owing to the tumor's secretion of calcitonin, and medullary cancer can also cause ectopic Cushing syndrome (Chapter 208).

Serum calcitonin levels are elevated. On ultrasound, most medullary cancers appear as hypoechoic nodules. Immunohistochemical staining of fine-needle aspiration biopsy material can detect calcitonin, chromogranin, and carcinoembryonic antigen (CEA).

Germline *RET* testing is recommended in newly diagnosed patients with apparently sporadic disease. When a germline mutation is discovered, genetic counseling and screening should be provided for first-degree relatives. Screening for metastases (using CT of the neck and chest, CT or MRI of the liver, and axial MRI or bone scintigraphy) is recommended in patients who have baseline serum calcitonin levels >500 pg/mL, an elevated CEA level, or a large burden of disease in the neck.

TREATMENT

Treatment is total thyroidectomy, but patients should be screened for pheochromocytoma (Chapter 209) and primary hyperparathyroidism (Chapter 227) preoperatively if they have a known germline *RET* mutation or if their *RET* mutation status is unknown. Central neck dissection should be performed in all cases. More extensive surgery is guided by the results of preoperative ultrasonography and scanning.

Thyroid hormone replacement is required following thyroidectomy; TSH-suppressive dosing is not indicated. Low or undetectable postoperative levels of serum calcitonin and a normal CEA are associated with a favorable prognosis, and patients can be followed with laboratory monitoring every 6 months. If the postoperative calcitonin levels are elevated but <150 mg/mL, neck ultrasonography should be performed. In patients with higher postoperative serum calcitonin levels (≥150 pg/mL), additional periodic imaging of the chest, liver, and skeleton is also recommended.

Treatment options for patients with recurrent or persistent disease include further surgical resection or directed therapies, including external beam radiation, radiofrequency ablation, and embolization. In addition, the multikinase inhibitors vandetanib (300 mg once daily) and cabozantinib (140 mg once daily) and the *RET*-selective kinase inhibitors selpercatinib (120 to 160 mg twice daily) and pralsetinib (400 mg once daily) are FDA-approved for patients who have advanced and progressive disease.[A11]

PROGNOSIS

The 10-year survival rates are 100% for stage I disease, 93% for stage II disease, 71% for stage II disease, and only 21% for stage IV disease. Survival rates are lower in individuals over age 40 years. A calcitonin doubling time of less than 6 to 12 months predicts poor survival.

Anaplastic Thyroid Cancer

Anaplastic thyroid cancer, which is a highly aggressive undifferentiated tumor derived from thyroid follicular cells, accounts for 1 to 2% of all thyroid cancers in the United States and up to 10% globally. It is more frequent in women, and the mean age at diagnosis is 65 years.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most patients present with a rapidly enlarging anterior neck mass, which may be painful and usually causes compressive symptoms. The trachea may be partially obstructed. Systemic symptoms may include weight loss, fatigue, and fever of unknown origin. Examination shows a large, firm, fixed, nodular goiter. Ultrasound generally shows a hypoechoic mass, but findings are nonspecific.

Rapid diagnosis is essential. Fine-needle aspiration biopsy is diagnostic in only about 60% of cases, so core biopsy is often required to establish the diagnosis.

Once the diagnosis is established, molecular profiling, particularly testing for *BRAF V600E* mutations, is recommended to inform therapeutic decisions. Radiologic staging should be performed with CT, MRI, or ^{18}FDG-PET scanning.

TREATMENT

Prompt treatment may be therapeutic or palliative, depending on the stage of disease and the patient's preferences.[34] Surgery, followed by chemotherapy, should be performed for tumors thought to be potentially resectable, although spread is usually extensive by the time of diagnosis.[35] In tumors with *BRAF V600E* mutations, neoadjuvant therapy with dabrafenib (150 mg twice daily) plus trametinib (2 mg once daily) may sufficiently decrease the tumor's size to make resection feasible. In tumors without *BRAF V600E* mutations, therapies targeted to specific tumor mutations (*ALK*, *NTRK*, or *RET* fusion mutations) may be effective. In the absence of a therapeutic response, palliative cytotoxic chemotherapy, radiation, or supportive hospice care may be elected.

PROGNOSIS

Metastatic anaplastic cancer is invariably fatal. The median survival in patients with anaplastic cancer is 5 to 6 months, and the 1-year overall survival is only 20%.

Primary Thyroid Lymphoma

Primary thyroid lymphoma is rare, with an annual incidence of 1 to 2 per million. Most primary thyroid lymphomas are B-cell lymphomas. The risk is increased 40- to 80-fold in the setting of Hashimoto thyroiditis. Most affected individuals are ages 60 to 69 years.

The clinical hallmark is rapid, painless, thyroid enlargement, often with associated compressive symptoms. Rapid enlargement from thyroid lymphoma must be differentiated from anaplastic carcinoma. Systemic symptoms of lymphoma (e.g., fever, night sweats, and weight loss) may be present.

Ultrasound may show either nodularity or diffuse thyroidal enlargement with heterogeneity. Fine-needle aspiration biopsy shows diffuse lymphocytic infiltration. Flow cytometry and immunohistochemical staining may establish the diagnosis, but open biopsy is occasionally required.

TREATMENT AND PROGNOSIS

Treatment with chemotherapy and radiotherapy under expert supervision yields 90% 5-year survival rates. Compressive symptoms typically improve with chemotherapy, and surgical resection is rarely required.

208 ADRENAL CORTEX

LYNNETTE K. NIEMAN

NORMAL ANATOMY AND FUNCTION

The adrenal glands weigh 6 to 8 g in adults (Fig. 208-1). Each contains a cortex, which makes steroid hormones, and a medulla, which produces catecholamines. Diseases of the adrenal medulla are discussed in Chapter 209. In the adrenal cortex, production of the three major classes of steroids occurs in specific zones: (1) the outermost layer, which is the glomerulosa, produces mineralocorticoids, primarily aldosterone; (2) the middle layer, which is the fasciculata, produces glucocorticoids, primarily cortisol; and (3) which is the innermost layer, the reticularis, produces adrenal androgens, primarily dehydroepiandrosterone (DHEA) and its sulfated conjugate (DHEA-S) (Fig. 208-2). This division reflects the fact that certain critical enzymes are restricted to specific zones, thereby resulting in the ability or inability to synthesize specific end products.

The actions and regulation of these steroid classes differ. Mineralocorticoids act through the renal mineralocorticoid receptor to promote the reabsorption of sodium and the secretion of potassium. In addition to this classic action, mineralocorticoids have important action on the vasculature and may exacerbate the metabolic syndrome. The secretion of aldosterone is stimulated primarily by hyperkalemia and angiotensin II (which itself is stimulated by hypovolemia and excess renin). These agents increase the production of aldosterone synthase to restore homeostasis through this feedback loop. Aldosterone production is stimulated to a much smaller degree by adrenocorticotropic hormone (ACTH).

Cortisol and other glucocorticoids act through the glucocorticoid receptor type 2 and its isoforms. The actions of this class of steroids are much broader, including effects on carbohydrate handling, lipid and calcium metabolism, and the immune and nervous systems. Cortisol production is regulated primarily by pituitary ACTH (Chapter 205), which is secreted in a circadian rhythm in response to hypothalamic corticotropin-releasing hormone (CRH; Chapter 204) so that cortisol levels are highest in the morning and fall to a nadir around midnight. Cortisol coordinates the production of ACTH through negative feedback at the pituitary (ACTH) and hypothalamus (CRH). Vasopressin secretion also plays a role in stimulating ACTH release.

DHEA and DHEA-S, which are the most abundant products of the adrenal gland, exert their estrogenic and androgenic effects as prohormones after being converted to estrogens and testosterone in the peripheral tissues, where they activate the androgen and estrogen receptors. There is no known regulator of DHEA synthesis, but its production declines with age.

DISORDERS OF ADRENAL FUNCTION

GLUCOCORTICOID EXCESS: CUSHING SYNDROME

EPIDEMIOLOGY

The annual incidence of Cushing syndrome is estimated to be between 1.8 and 3.2 cases/million.[1] It is more common in women than in men (6 : 1 ratio), with a mean age at onset in the fourth decade.

PATHOBIOLOGY

Most disorders of the adrenal cortex reflect overproduction or underproduction of the products of a single synthetic zone—cortisol, aldosterone, or testosterone or estrogen (Fig. 208-3). The congenital adrenal hyperplasias, which are an exception, manifest with both overproduction and underproduction. Abnormal secretion is suggested by clinical features of each disorder and is reflected in plasma or urine levels of the relevant hormones or by the consequent increases or decreases in feedback systems, which form the basis of the biochemical diagnostic tests.

In Cushing syndrome, higher brain pathways stimulate the release of CRH and activation of the entire hypothalamic-pituitary-adrenal axis (see Fig. 208-3E). Cortisol negative feedback inhibition on CRH and pituitary ACTH release restrains the resulting hypercortisoluria to less than four-fold greater than normal.

In Carney syndrome, in which hyperfunctioning adrenal nodules cause Cushing syndrome, myxomas, and spotty skin pigmentation, patients have mutations that lead to a truncated form of protein kinase A regulatory 1α subunit. The resultant increase in protein kinase A activation by cyclic adenosine monophosphate presumably allows tumor formation. In bilateral macronodular adrenal hyperplasia, aberrant expression of "illicit" receptors for various ligands (gastric inhibitory polypeptide, β-adrenergic, vasopressin) presumably mediates autonomous cortisol production.

CLINICAL MANIFESTATIONS

Cushing syndrome is a symptom complex that reflects excessive exposure of tissues to cortisol. Classic features of Cushing syndrome include weight gain, plethora, hypertension, and striae (Table 208-1). Not all patients have all features; the number and severity of features correlate roughly with the duration and severity of hypercortisolism. Changes in mood and cognition include irritability, crying, and restlessness; depressed mood; decreased libido; insomnia; anxiety; and decreased concentration and impaired memory.

Because many of the signs and symptoms are nonspecific, the diagnosis may be confused with psychiatric disorders (Chapter 362), polycystic ovary syndrome (Chapter 218), the metabolic syndrome (Chapter 210), simple obesity (Chapter 201), fibromyalgia, or acute illness. However, because worsening hypercortisolism may precipitate hypertension, glucose intolerance, infections, psychiatric disturbances, impaired cognition, and hypercoagulability,

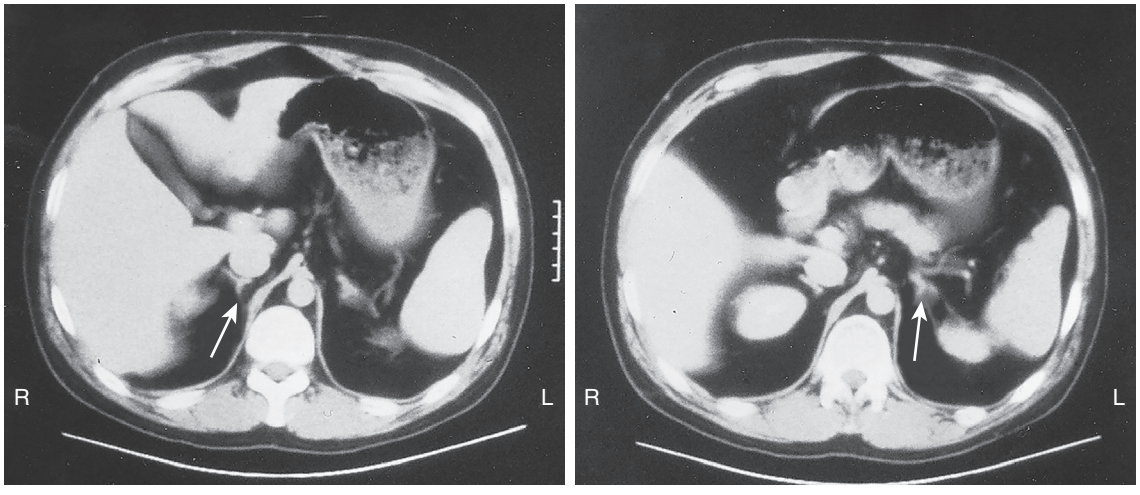

FIGURE 208-1. Magnetic resonance images of the abdomen showing the position and relative size of the normal adrenal glands.

ABSTRACT

The adrenal glands contain the cortex, which makes steroid hormones, and the medulla, which produces catecholamines. In the adult human adrenal cortex, production of the three major classes of steroids occurs in specific zones: the outermost layer, the glomerulosa, produces mineralocorticoids, primarily aldosterone; the middle layer, the fasciculata, produces glucocorticoids, primarily cortisol; the innermost layer, the reticularis, produces adrenal "androgens," primarily dehydroepiandrosterone (DHEA) and its sulfated conjugate (DHEA-S). Most disorders of the adrenal cortex reflect overproduction or underproduction of the products of a single synthetic zone—cortisol, aldosterone, or testosterone or estrogen. The congenital adrenal hyperplasias are an exception and manifest with both overproduction and underproduction. Abnormal secretion is suggested by clinical features of each disorder and is reflected in plasma or urine levels of the relevant hormones or by the consequent increases or decreases in feedback systems, which form the basis of the biochemical diagnostic tests. Current diagnostic and treatment recommendations are presented for hypercortisolism and hypocortisolism (Cushing syndrome and adrenal insufficiency), mineralocorticoid and adrenal androgen excess, and combined excess and deficiencies seen in congenital adrenal hyperplasias.

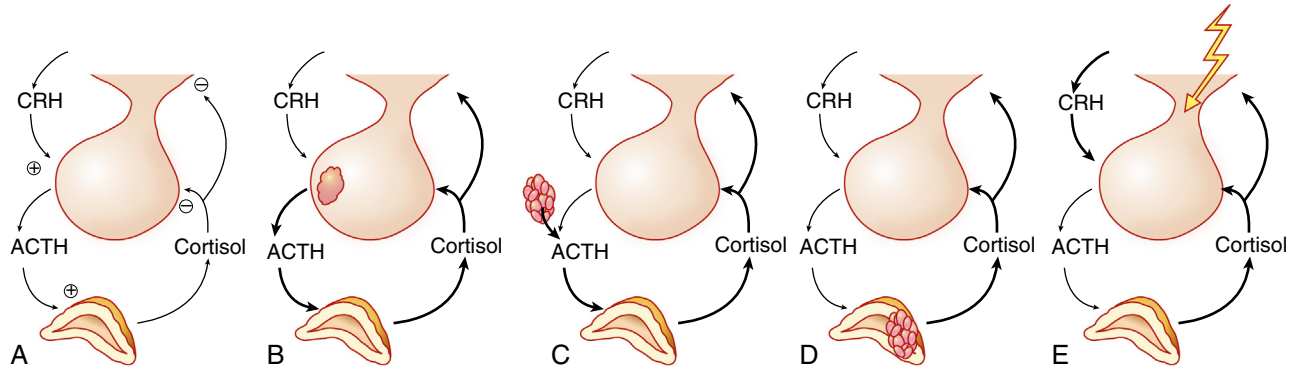

FIGURE 208-3. **Physiology of the adrenal axis in health, Cushing syndrome, and pseudo-Cushing states. A,** In healthy individuals, cortisol production is stimulated by the increased hypothalamic release of corticotropin-releasing hormone (CRH), which then travels down the pituitary stalk to stimulate adrenocorticotropic hormone (ACTH) secretion and release by corticotropes. Circulating ACTH stimulates adrenal gland production and secretion of cortisol. Cortisol then functions in a negative feedback mechanism to inhibit both CRH and ACTH. **B,** In Cushing disease, a pituitary tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **C,** In ectopic ACTH secretion, a nonpituitary ACTH-secreting tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **D,** In ACTH-independent adrenal forms of Cushing syndrome, the adrenal tumor autonomously releases excess amounts of cortisol. In all forms of Cushing syndrome, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that circulating ACTH levels reflect the underlying tumor (levels are normal or increased) or independent cortisol production (levels are suppressed). **E,** In pseudo-Cushing states, central stimulation increases CRH secretion, which in turn increases ACTH and hence cortisol production. In this setting, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that cortisol levels are ultimately constrained, albeit at an increased level.

it is important to identify this treatable disorder to prevent its associated morbidity and mortality.[2]

DIAGNOSIS

Clinical Examination

Screening for Cushing syndrome is most likely to be positive in the presence of signs that are typical of glucocorticoid excess, such as abnormal fat distribution in the supraclavicular and temporal fossae, proximal muscle weakness, wide (>1 cm) purple striae, and new irritability, decreased cognition, and decreased short-term memory. Testing is indicated when clinical features have progressed over time and in patients with adrenal masses that are incidentally detected on imaging obtained for unrelated reasons (so-called adrenal incidentalomas).[3,4] For example, oligomenorrhea is more suggestive of Cushing syndrome if a woman previously had regular menses. Serial seven subtractions and recall of three cities (or objects) are useful bedside strategies to identify deficits in cognition and memory.

Laboratory Findings

Exogenous glucocorticoid exposure should be excluded before screening for endogenous Cushing syndrome. Pseudo-Cushing states include psychiatric disorders (depression, anxiety disorder, obsessive-compulsive disorder), chronic pain, severe exercise, alcoholism, uncontrolled diabetes, and morbid obesity. In the absence of these conditions, at least two different screening tests, all of which have similar diagnostic accuracy (Fig. 208-4),[5] should be abnormal to establish the diagnosis of Cushing syndrome. Importantly, tests that are

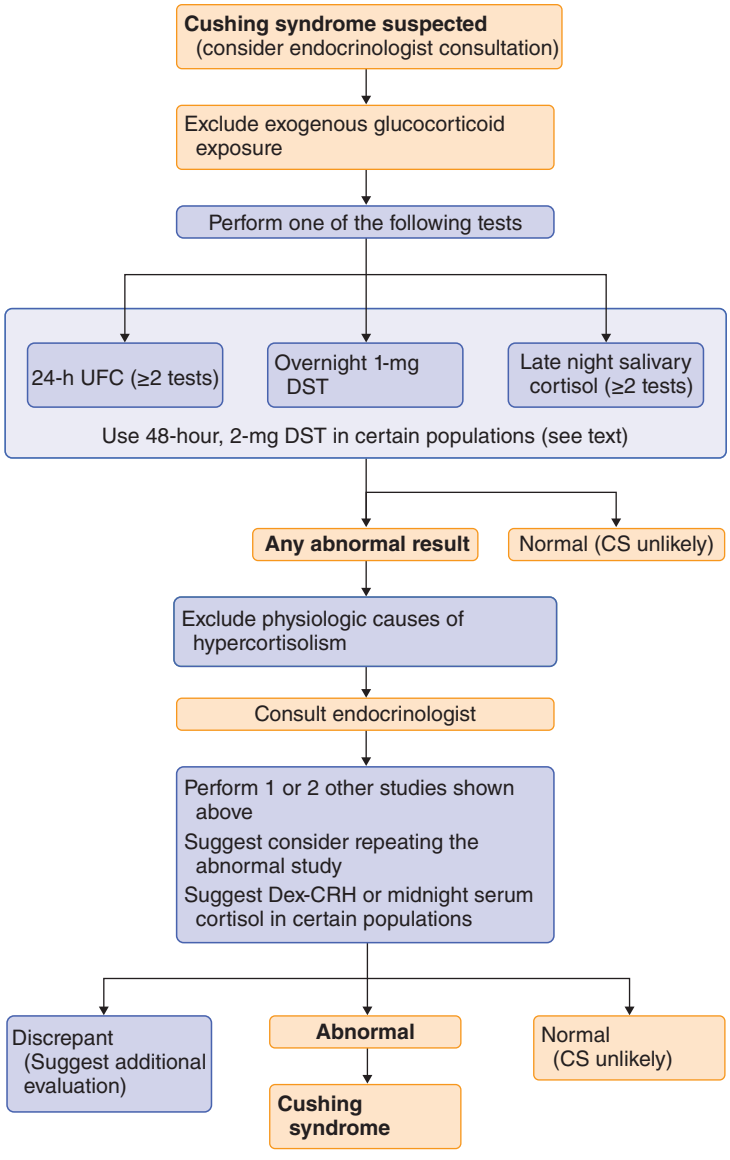

FIGURE 208-4. Algorithm for testing of patients suspected of having Cushing syndrome (CS). All statements are recommendations except for those prefaced by "suggest." Diagnostic criteria that suggest Cushing syndrome are urine free cortisol (UFC) greater than the normal range for the assay, serum cortisol greater than 1.8 μg/dL (50 nmol/liter) after 1 mg dexamethasone (1-mg DST), and late-night salivary cortisol greater than 145 ng/dL (4 nmol/liter). Dex-CRH = dexamethasone–corticotropin-releasing hormone test; DST = dexamethasone suppression test. (Reprinted with permission from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing syndrome: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2008;93:1526-1540.)

useful for diagnosing the specific cause of Cushing syndrome should not be used to make the syndromic diagnosis.

Urine and Saliva Cortisol Measurements

Urine free cortisol excretion during 24 hours is elevated in about 20% of adrenal incidentalomas (see later) and also may be increased in the so-called pseudo-Cushing states. Cushing syndrome cannot be diagnosed with certainty unless values reach the threshold of exceeding four times the normal values. Conversely, patients with Cushing syndrome may have normal urine free cortisol excretion because of mild or intermittent hypercortisolism or altered renal metabolism of cortisol. If urine free cortisol levels are only mildly elevated and clinical features are minimal, it is best to treat any pseudo-Cushing state and to remeasure the levels, with the expectation that they will normalize. Alternatively, if urine free cortisol values are normal but clinical suspicion is high, repeated measurement might disclose intermittent hypercortisolism.

Measurement of bedtime salivary cortisol is a convenient outpatient test.[6] Because the assay is technique influences the results, criteria for its interpretation differ, and each assay must be validated before it is used for this purpose.

TABLE 208-2 ETIOLOGY OF CUSHING SYNDROME

EXOGENOUS	ENDOGENOUS
Most common cause of Cushing syndrome: Glucocorticoid or ACTH driven May be factitious or iatrogenic	ACTH independent—autonomous adrenal activation (20% of all cases) • Adrenal adenoma (40-50%) • Adrenal carcinoma (40-50%) • Primary pigmented nodular adrenal disease • McCune-Albright syndrome • Primary Bilateral macronodular adrenal hyperplasia ACTH dependent—adrenal activation by excessive ACTH (80% of all cases) • Corticotrope adenoma (80%) • Ectopic ACTH secretion (20%) • Ectopic CRH secretion (rare)

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

Dexamethasone Suppression Tests

The dexamethasone suppression test is a simple screening test that takes advantage of the negative feedback effect of glucocorticoids to reduce ACTH (and hence serum cortisol). Dexamethasone 1 mg is given orally between 11:00 PM and midnight, and then plasma cortisol is measured between 8:00 and 9:00 AM the next morning. Using a cutoff value of 1.8 μg/dL, the test has a false-negative rate of up to about 10% in patients with Cushing syndrome and a false-positive rate of up to about 30 to 50% in patients without the condition.[7]

Any dexamethasone test may give false results in patients who have abnormal metabolic clearance of the drug. Agents that induce the cytochrome P-450 CYP3A4 enzymes (alcohol, rifampin, phenytoin, phenobarbital) increase dexamethasone clearance, whereas renal or hepatic failure decreases it. Measurement of a dexamethasone level can determine whether its clearance has been altered.

Differential Diagnosis

The causes of endogenous Cushing syndrome can be divided broadly into ACTH-dependent (80%) and ACTH-independent (20%) forms (Table 208-2 and Fig. 208-5). Hypercortisolism from autonomously functioning benign or malignant adrenal tumors suppresses ACTH, whereas ACTH levels are elevated when the adrenal glands respond to ACTH from a pituitary adenoma or extra-adrenal tumor. A normal or elevated plasma ACTH level (>15 pg/mL; 3.3 pmol/L) is consistent with an ACTH-producing tumor. Intermediate ACTH concentrations between 5 and 15 pg/mL (1.1 to 3.3 pmol/L) are not diagnostic; in such patients, suboptimal cortisol responses to CRH stimulation may identify the minority of cases of ACTH-independent Cushing syndrome with borderline basal ACTH values. In addition, a suppressed plasma DHEA-S value supports the diagnosis of an ACTH-independent disorder.

Primary Adrenal Disorders

ACTH is usually less than 10 pg/mL in primary adrenal disorders but is also suppressed by exogenous steroids, whether they are prescribed intentionally (iatrogenic Cushing syndrome) or taken factitiously. Patients must be queried closely about exogenous steroid administration, recognizing that oral, parenteral, inhaled, and topical steroids can all cause glucocorticoid excess. Patients with endogenous Cushing syndrome and low ACTH concentrations should undergo adrenal imaging to identify the site of adrenal abnormality. Nonautonomous adrenal tissue atrophies when ACTH support is subnormal, so the common ACTH-independent forms of Cushing syndrome (adrenal adenoma and carcinoma) manifest as a unilateral adrenal mass, with atrophy of the adjacent and contralateral tissue on magnetic resonance imaging (MRI) or computed tomography (CT).

Adrenal Adenoma

Adrenal adenomas, which secrete only cortisol and its precursors, present with features that range from clinically obvious Cushing syndrome with unequivocal diagnostic results, to a more subtle clinical picture with fewer biochemical abnormalities. This latter presentation may come to attention only when imaging for another reason uncovers an adrenal "incidentaloma" and diagnostic testing returns only an abnormal 1 mg dexamethasone suppression test. Although previously termed subclinical Cushing syndrome, this condition has been re-named mild autonomous cortisol excess because these patients often have features compatible with Cushing syndrome, and have increased cardiovascular mortality.[8]

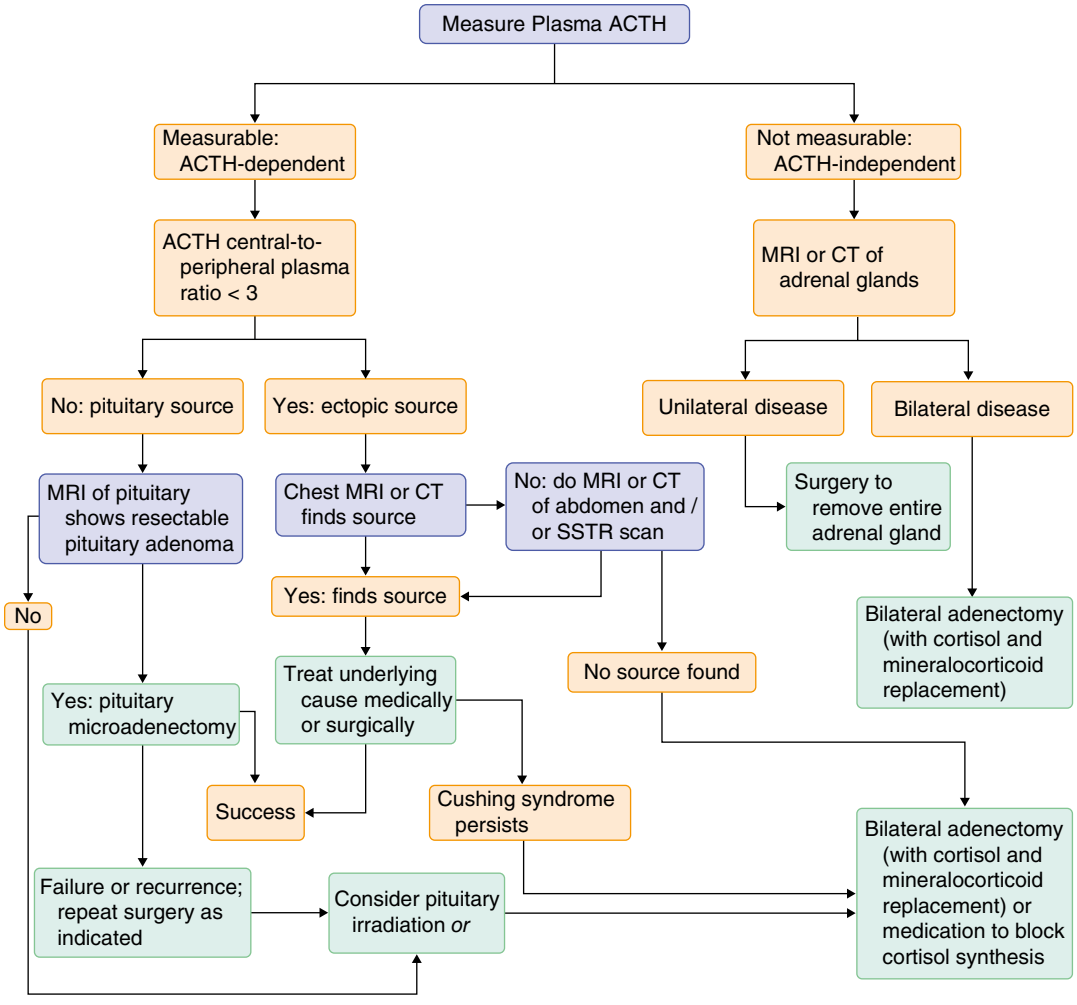

FIGURE 208-5. Approach to the differential diagnosis and treatment of Cushing syndrome. ACTH = adrenocorticotropin hormone; CT = computed tomography; MRI = magnetic resonance imaging; SSTR = somatostatin receptor scan.

Adrenal Cortical Cancer

Adrenal cortical cancer can present with hormonal excess of one or more layers of the adrenal cortex, with pure glucocorticoid excess (Cushing syndrome) being most common, followed by glucocorticoid and androgen excess (Cushing syndrome with virilization), and rarely as a pure excess of estrogen, androgen, or mineralocorticoids. Alternatively, adrenal cortical cancer may be hormonally silent and present with mass effects. In addition to measurement of adrenal cortex hormones and their precursors, imaging provides important clues to malignancy, including pre-contrast CT Hounsfield units more than 25, irregular margins, size greater than 4 cm, necrosis, or calcifications.

Bilateral Primary Adrenal Disease

Bilateral forms of primary adrenal disease are rare and may be manifested with small or large adrenal nodules. Primary pigmented nodular adrenal disease, which occurs primarily in children and young adults, is characterized by small- to normal-sized adrenal glands containing small (<5 mm) black-brown cortical nodules. About half of these patients have additional features, termed *Carney complex*, which are often inherited in an autosomal dominant fashion.[9] The clinical features of Carney complex include myxomas of the skin, breast, and heart; spotty pigmentation, such as lentigines and blue nevi; and other endocrine overactivity, such as acromegaly and testicular tumors. Bilateral nodular hyperplasia with Cushing syndrome can occur in the setting of McCune-Albright syndrome, mostly in infants or children. Bilateral macronodular adrenal hyperplasia generally is manifested after the age of 40 years with huge adrenal glands.

Excess ACTH

Cushing disease, which is almost always caused by an ACTH-secreting pituitary adenoma (Chapter 205), is the most common cause of Cushing syndrome. ACTH also may be secreted ectopically by a variety of neuroendocrine tumors (Table 208-3). Rarely, CRH from nonpituitary (ectopic) tumors may stimulate excess ACTH secretion from the pituitary or may be secreted along with ACTH from these tumors.

TABLE 208-3 THE INCIDENCE AND TYPES OF TUMORS CAUSING THE SYNDROME OF ECTOPIC ACTH SECRETION

TUMOR TYPE	PERCENTAGE
Carcinoma of lung (small cell or oat cell)	19-50

Pancreatic neuroendocrine tumor	4-12
Pheochromocytoma, neuroblastoma, ganglioma, paraganglioma	5-12
Medullary carcinoma of the thyroid	0-5
Miscellaneous*	<1

*Miscellaneous tumors reported to secrete ACTH in 1-10 cases include carcinoma or neuroendocrine tumor of the ovary, prostate, breast, thyroid, kidney, salivary glands, testes, gallbladder, esophagus, stomach, kidney and appendix; acute myeloblastic leukemia; melanoma; and cloacogenic carcinoma of the anal canal.
ACTH = adrenocorticotropic hormone.

Pituitary MRI shows a tumor in only about 40 to 50% of patients with Cushing disease, but it should be obtained routinely in patients with ACTH-dependent disease to exclude a macroadenoma or abnormal anatomy before petrosal sinus sampling or surgery. A pituitary lesion less than 6 mm is seen in up to 10% of healthy individuals and so does not always indicate Cushing disease.

Inferior petrosal sinus sampling, which has a sensitivity and specificity of about 94%, is the best test to distinguish between a pituitary and an ectopic source of excess ACTH. The test involves catheterization of a peripheral vein and also the petrosal sinuses draining the pituitary gland; simultaneous measurement of ACTH levels at each site before and 3, 5, and 10 minutes after administration of CRH; and calculation of the central-to-peripheral ACTH

ratio at each time point. Ratios of more than 2 before CRH administration or more than 3 after CRH administration are consistent with Cushing disease. When CRH is not available, desmopressin is used as a substitute, either in the peripheral test or with inferior petrosal sinus sampling, despite its lower sensitivity for Cushing disease.

Unfortunately, inferior petrosal sinus sampling carries a small risk of stroke, is expensive, and is not widely available. Other tests, such as the CRH test, the desmopressin test, and the 8-mg dexamethasone suppression test (Chapter 205), may be useful if both responses indicate Cushing disease. In this setting, the likelihood of ectopic ACTH secretion is low. However, the diagnosis is not clear if both responses are negative or if they are mixed.

If endocrine tests suggest ectopic ACTH secretion, potential tumor sources include small cell lung cancer (Chapter 177), pulmonary neuroendocrine tumors (Chapter 204), medullary thyroid cancer (Chapter 207), islet cell tumors (Chapter 211), and pheochromocytomas (Chapter 209) or paragangliomas (Chapter 213). Thin-cut CT or MRI of the chest is the best initial screens because in aggregate these tumors are most often in the thoracic cavity (see Table 164-5). Imaging that detects expression of somatostatin receptors 2 and 5 on these tumors (octreotide scintigraphy or DOTATATE/DOTANOC-PET) is a useful adjunctive test. Measurement of serum calcitonin and gastrin, as well as of plasma or urine catecholamines, may identify medullary carcinoma of the thyroid, gastrinoma, and pheochromocytoma. The process can be repeated every 6 to 12 months; tumors that make ACTH ectopically have a spectrum of malignant potential, and annual screening should continue, regardless of treatment for hypercortisolism.

TREATMENT

Surgical Therapy

The optimal treatment of Cushing syndrome is surgical resection of the lesion(s) that is producing excessive ACTH or cortisol. If such surgery is unsuccessful or cannot be done, bilateral adrenalectomy is an option.

Pituitary Adenoma

Transsphenoidal resection of a microadenoma is the optimal therapy for a patient with Cushing disease, with up to a 90% chance of cure by an experienced neurosurgeon (Chapter 205). A successful outcome is less likely if the initial surgery is not curative, in cases of recurrence, and for macroadenomas. Controversy exists about the criteria for remission; although a low postoperative cortisol level is encouraging, it does not preclude later recurrence. If recurrence develops, additional resection or alternative therapy should be considered.

Adrenal Adenoma or Tumor

Nonmalignant primary adrenal causes of overt Cushing syndrome are cured by resection of the abnormal tissue. Laparoscopy is the preferred approach. The role of surgery to reduce morbidity and mortality of patients with mild autonomous adrenal excess is controversial, because no prospective studies have been reported. Surgery is the mainstay in the treatment of adrenal cancer[10]; multiple operations may be needed to resect primary lesions, local recurrences, and hepatic, thoracic, and intracranial metastases. Adjuvant adrenolytic therapy with mitotane, with doses to achieve serum levels of 14 to 20 mg/L, may provide a chemotherapeutic benefit.

Ectopic ACTH

Patients with ectopic ACTH secretion can be cured if the tumor is not metastatic and can be removed. Otherwise, adrenalectomy or medical therapy is required. Adrenalectomy is appropriate when the patient cannot tolerate the medical toxicity, cost, or adverse psychological effects of long-term medical therapy and monitoring; when rapid correction of hypercortisolism is needed; or if maximal daily doses of ketoconazole (1600 mg) and metyrapone (6 g) given in combination do not render the patient eucortisolemic.

Role of Bilateral Adrenalectomy

Adrenalectomy is an option when the source of excess ACTH cannot be removed surgically. It provides rapid normalization of hypercortisolism, so it may be chosen by patients who have concerns about radiation-induced hypopituitarism or adherence to medications or by women who desire fertility in the near future.

Radiation Therapy

Radiation therapy to the pituitary gland, with adjunctive medical therapy to normalize cortisol levels, is an option for Cushing disease in patients who cannot undergo surgery, in patients in whom the risk of Nelson syndrome (Chapter 205) is deemed great (especially if they have local tumor invasion), and patients who have recurrent disease. Radiation can be delivered in 200-rad daily increments to a total dose of 45 Gy, or by high-energy gamma or proton radiosurgery in only one or two treatments to achieve a similar total dose. The disadvantage of radiation therapy is the length of time needed for a full response—up to 10 years—and the likelihood of panhypopituitarism.

Medical Therapy

Medical therapy is used for patients who have occult or unresectable ectopic ACTH-secreting tumors. It can also be used in combination with pituitary irradiation to treat unresectable or persistent pituitary tumors or ACTH-independent Cushing syndrome.[11]

For an ACTH-producing pituitary tumor, cabergoline (1 to 7 mg 2 to 7 times weekly) or pasireotide[A1] (600 or 900 μg subcutaneously daily or 10 or 30 mg once monthly) can normalize urine free cortisol in about 40% of patients. For all causes of Cushing syndrome, metyrapone (500 mg to 6 g per day), osilodrostat[A2] (4 to 60 mg per day), ketoconazole (600 to 1600 mg per day), and levoketoconazole (starting at 150 mg twice daily and increasing in 150-mg increments to a maximum of 600 mg twice daily until the urine free cortisol level normalizes) act at the adrenal gland to reduce cortisol production. Mifepristone (300 to 1200 mg per day), which is a glucocorticoid antagonist, may be used for either ACTH-dependent or ACTH-independent disease. Any type of medical therapy requires close monitoring and adjustment of the dose to maintain urine free cortisol in the normal range. There are limited data on the long-term efficacy of any medical therapy in Cushing syndrome.

Adrenocortical Carcinoma

Although surgery is the mainstay of treatment, mitotane (titrated to the maximal tolerated dose to maintain serum levels of 14 to 20 mg/L) treatment and radiation therapy may be recommended, depending on the stage of the disease and other prognostic factors. After complete resection, the recurrence of adrenocortical carcinoma is more common in patients who had a larger tumor size, venous tumor thrombus, and the proliferation tumor marker Ki67. For advanced adrenocortical carcinoma, rates of response and progression-free survival but not overall survival are significantly better with first-line therapy using a combination of etoposide (100 mg/m^2 on days 2 to 4), doxorubicin (40 mg/m^2 on day 1), and cisplatin (40 mg/m^2 on days 3 and 4) plus oral mitotane (to achieve a blood level of 14 to 20 mg/L) than with streptozocin plus mitotane, with similar rates of toxic events.

PROGNOSIS

Patients with Cushing disease usually can be cured by transsphenoidal surgery (Chapter 205), but have about a 2.5-fold increased risk of mortality. The major cause is cardiovascular disease, but the risks of infections and suicide are also increased.[12] For ectopic ACTH syndromes, the prognosis depends on the underlying disease. Benign unilateral adrenal adenomas and bilateral benign adrenal disease do not recur. For adrenal carcinoma, the mortality rate varies according to the grade of the tumor and the stage of disease at initial resection.

After pituitary surgery or unilateral adrenalectomy, patients require replacement glucocorticoids (generally hydrocortisone) until the hypothalamic-pituitary-adrenal axis recovers, which usually occurs within 6 to 24 months after of surgery. Some but not all patients may require glucocorticoid replacement after radiation therapy if decreased ACTH secretion from the tumor and normal corticotropes results in adrenal insufficiency. After bilateral adrenalectomy, patients require lifelong glucocorticoid and mineralocorticoid replacement. For patients who are receiving replacement glucocorticoids, additional doses of are needed during physical stress (e.g., trauma or surgery; see Treatment of Adrenal Insufficiency).

ADRENAL INCIDENTALOMA

Adrenal incidentalomas[13] are defined as abnormalities seen on imaging, typically ordered for an unrelated indication, in the absence of meeting criteria for Cushing syndrome. The evaluation should determine its hormonal activity (see Fig. 208-4). Mild autonomous hypercortisolism may be diagnosed in 30 to 50% of cases, and about 5 to 8% of incidentalomas may be malignant.[14] A consistent level above 83 nmol/L after 1 mg of dexamethasone suppression (mild autonomous cortisol excess) is associated with a two-fold or more increase in mortality.[15] Adrenal incidentalomas without a mild excess in cortisol secretion have a benign prognosis. Average growth over 4 or so years is only 2 mm, and clinical progression is rare.[16]

MINERALOCORTICOID EXCESS

EPIDEMIOLOGY

The prevalence of primary aldosteronism increases as hypertension becomes more severe, especially in patients ages 30 to 39 years, in whom up to 30% may have the condition; prevalence varies depending on the population studied: in one cross-sectional study, rates in were as high as about 13% in the primary care setting and 30% in hypertension referral practices.[17–19]

PATHOBIOLOGY

Mineralocorticoid excess can result from primary adrenal disease, in which aldosterone (or another mineralocorticoid) is produced autonomously (and renin levels are low), or it may be due to nonadrenal causes as a result of elevated renin values, which stimulate aldosterone secretion. The latter situations include states of contracted arterial intravascular volume, such as heart failure or cirrhosis with ascites, decreased renal arterial blood flow, and tumor production of renin (Table 208-4).

Familial hyperaldosteronism type 1 is caused by a genetic swap of the promoter for *CYP11B1* (11β-hydroxylase) with that of *CYP11B2* (aldosterone synthase), thereby forming a chimeric gene in which ACTH stimulates aldosterone synthase. Mutations in the *CLCN2* gene that encodes a voltage-gated chloride channel that is expressed in adrenal glomerulosa cells are found in rare early-onset familial hyperaldosteronism type 2. Somatic mutations in six genes account for nearly 90% of aldosterone-producing adenomas, with varying frequency according to sex and race.[20]

TABLE 208-4 CAUSES OF MINERALOCORTICOID EXCESS

PRIMARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, LOW RENIN
Aldosterone-producing adenomas (30-50%)
Bilateral zona glomerulosa hyperplasia
Familial hyperaldosteronism
Type 1: glucocorticoid-remediable hyperaldosteronism—this results from formation of a chimeric gene containing the regulator portion of 11β-hydroxylase (normally regulated by ACTH) and the synthetic region of aldosterone synthase; as a result, ACTH stimulates aldosterone synthase and hence aldosterone production
Type 2: adrenal adenomas or hyperplasia expressed in a familial pattern
Type 3: caused by mutant *KCNJ5*, often younger and more severe than type 2
Aldosterone-producing adrenal carcinoma
Ectopic aldosterone secretion (rare): kidney, ovary
SECONDARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, HIGH RENIN
Renovascular hypertension and aortic stenosis
Diuretic use
Renin-secreting tumors
Severe cardiac failure
APPARENT MINERALOCORTICOID EXCESS: LOW ALDOSTERONE, LOW RENIN
Licorice ingestion: licorice (candy or flavored tobacco) containing glycyrrhetinic acid (or similar compounds such as carbenoxolone) inhibits renal 11β-hydroxysteroid dehydrogenase type 2, reducing cortisol conversion to cortisone and enabling cortisol to act as an endogenous mineralocorticoid
Severe hypercortisolism: similar in mechanism to licorice ingestion; very high cortisol levels are thought to overwhelm the ability of 11β-hydroxysteroid dehydrogenase type 2 to convert cortisol to cortisone in the kidney; cortisol itself then acts as a potent mineralocorticoid
Liddle syndrome: mutation of the gene for the β or γ subunit of the collecting tubule sodium channel leads to a constitutive increase in sodium reabsorption and potassium excretion
11β-Hydroxylase deficiency form of congenital adrenal hyperplasia: 11-deoxycortisol accumulates because of an inability to convert it to cortisol
17-Hydroxylase deficiency form of congenital adrenal hyperplasia: deoxycorticosterone and corticosterone are increased

CLINICAL MANIFESTATIONS

Patients with mineralocorticoid excess often have few clinical symptoms apart from fatigue and muscle weakness or cramps related to hypokalemia. Most often the condition is suspected because of hypertension (Chapter 64), especially if it occurs at an early age in association with spontaneous hypokalemia or is difficult to control. Biochemically overt renin-independent aldosterone production spans a clinical spectrum from normal blood pressure and potassium level to hypokalemia and hypertension.[21]

DIAGNOSIS

Although excessive aldosterone production by one or both adrenal glands causes most of these conditions, excessive production of other mineralocorticoids or constitutive activation of the renal sodium channel must be excluded. In these latter conditions, both aldosterone and renin values are low, resulting in the so-called syndrome of apparent mineralocorticoid excess. In this setting, diagnostic information is obtained by history (licorice ingestion) or measurement of other mineralocorticoids (see Table 208-4).

Primary hyperaldosteronism is diagnosed when there is an increased ratio (>20) of morning aldosterone to plasma renin activity (Fig. 208-6). Except as noted in the figure, one of four tests (usually salt loading) is used to confirm primary hyperaldosteronism by demonstrating a lack of aldosterone suppression.

Differential Diagnosis

After making the diagnosis of aldosterone-dependent mineralocorticoid excess, the next step is to differentiate between the two most common adrenal causes, which are hyperplasia and adenoma. In the presence of a strong family history, however, the possibility of rare familial causes of hyperaldosteronism can be confirmed by genetic testing (see http://www.brighamandwomens.org/Departments_and_Services/medicine/services/endocrine/Services/gra/default.aspx). For the more common causes, adrenal CT scans may show nonfunctioning nodules and falsely suggest an adenoma. However, further testing is not recommended if the patient is less than age 35 years and has

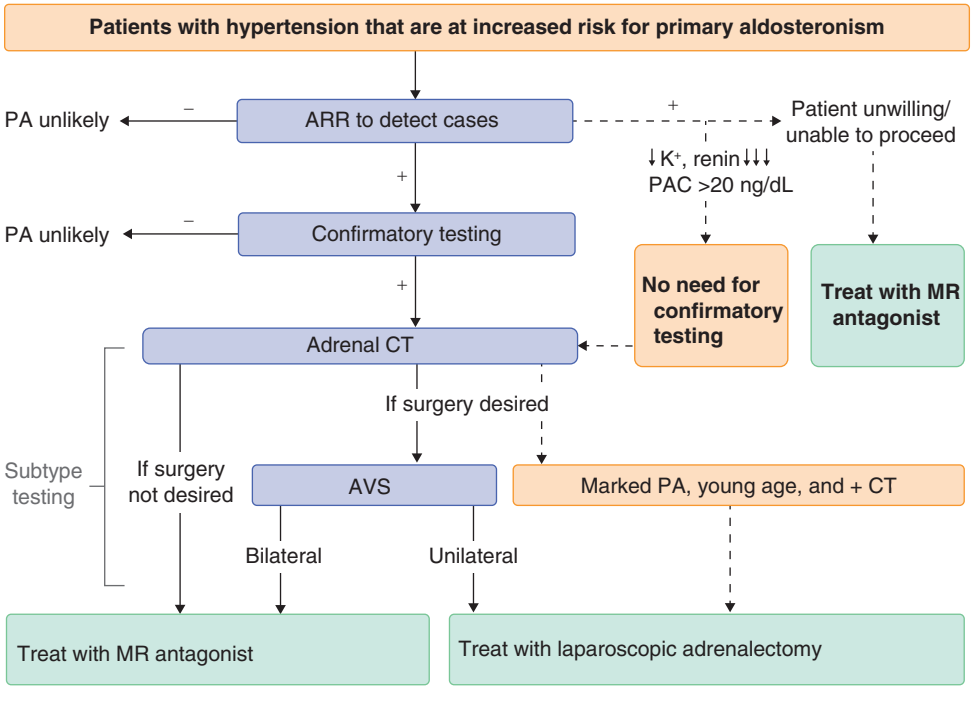

FIGURE 208-6. Algorithm for the diagnosis and treatment of primary aldosteronism (hyperaldosteronism). ARR = aldosterone-to-renin ratio; AVS = adrenal venous sampling; CT = computed tomography; MR = mineralocorticoid receptor; PA = primary aldosteronism; PAC = plasma aldosterone concentration. (Reprinted, with slight modification of text, from Funder JW, Carey RM, Mantero F, et al. The management of primary aldosteronism: case detection, diagnosis, and treatment: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2016;101:1889-916.)

marked aldosteronism with an adrenal mass. The responses to physiologic maneuvers such as upright posture, and salt loading with oral or intravenous sodium, tend to be preserved in patients with hyperplasia, but there is significant overlap among groups of patients. The best diagnostic test involves the measurement of cortisol and aldosterone in bilateral adrenal venous effluent and a peripheral vein before and during an ACTH infusion.[22] Cortisol is used to evaluate catheter placement in the adrenal veins, as levels from the two sides should be similar. When an adenoma is present, the aldosterone-to-cortisol ratio on one side is usually at least five-fold greater than the other, which may be similar to the periphery, indicating suppression. Bilateral hyperplasia tends to produce similar values on each side.

TREATMENT

Treatment of primary hyperaldosteronism includes laparoscopic or robotic resection for adenomas. Afterward, hypokalemia generally resolves, but hypertension persists in up to 65% of patients. A mineralocorticoid antagonist (e.g., spironolactone [12.5 to 25 mg daily and titrated every 2 weeks upward to achieve normal blood pressure] or eplerenone [50 mg daily and titrated upward]) is used to treat patients who are unable to undergo surgery or who have bilateral hyperplasia. Eplerenone is a more selective mineralocorticoid antagonist (with fewer side effects of sexual dysfunction and gynecomastia compared with spironolactone). A sodium channel blocker (e.g., amiloride, 5 to 10 mg daily) may be helpful, and antihypertensive agents are continued as needed (Chapter 64).

ANDROGEN EXCESS

PATHOBIOLOGY

The adrenal causes of hyperandrogenism—congenital adrenal hyperplasia, Cushing disease, adrenal cancer, and androgen-producing adrenal adenoma—are uncommon. Most women have no clear-cut cause (idiopathic hirsutism) or polycystic ovary syndrome (Chapter 218). Rarely, androgen-secreting ovarian tumors, hyperprolactinemia, glucocorticoid resistance, or exogenous drugs cause hyperandrogenism. DHEA and DHEA-S are weak androgens that can be converted locally to testosterone in the hair follicles.

CLINICAL MANIFESTATIONS

Women with excess circulating androgens or increased sensitivity to androgens present with complaints of hirsutism, acne, and anovulation or infertility. When testosterone is secreted in great excess, women may virilize and exhibit a deepened voice, clitoromegaly, masculinized body habitus, and alopecia.

DIAGNOSIS

Patients with an adrenal source of hyperandrogenism usually have increased serum levels of DHEA, DHEA-S, or androstenedione, in contrast to the testosterone excess that is more typical of an ovarian source. Because DHEA and DHEA-S levels decline throughout adult life, these values must be interpreted within age-specific normal ranges. A tumor is more likely if DHEA-S is greater than 500 μg/dL or testosterone is greater than 200 ng/mL, but it is not excluded at lower levels.

Imaging identifies nearly all adrenal tumors but may miss a small intraovarian tumor. Urine free cortisol may be elevated in patients with virilizing adrenal carcinoma or Cushing disease (see earlier) and in patients with glucocorticoid resistance. By contrast, androgen-secreting adrenal adenomas do not have glucocorticoid excess. In women suspected of having nonclassic forms of congenital adrenal hyperplasia (see later), precursor and product hormones should be measured before and after ACTH to confirm the diagnosis.

TREATMENT

Treatment of adrenal causes of hyperandrogenism varies according to the disorder. Classic congenital adrenal hyperplasia is treated by glucocorticoids to normalize ACTH (typically dexamethasone 0.125 to 0.375 mg at bedtime) and hence androgen levels. The nonclassic forms respond well to an oral contraceptive (e.g., 20 μg or less of ethinyl estradiol) or to antiandrogen treatment (e.g., spironolactone 50 to 100 mg twice daily in the United States; cyproterone acetate 50 to 100 mg daily elsewhere) with clomiphene citrate or gonadotropins reserved for the induction of ovulation. Surgery with adjunctive medical treatment may be used in adrenal carcinoma (see earlier).

ADRENAL INSUFFICIENCY

EPIDEMIOLOGY

The prevalence of noniatrogenic adrenal insufficiency is about 100 per million in the population. In adults in industrialized countries, autoimmunity is by far the most common form, followed by infection, which is relatively more common in low income countries.

PATHOBIOLOGY

Primary Adrenal Insufficiency

Autoimmune Destruction

Autoimmune destruction of the adrenal gland usually occurs in isolation. Rarely, it occurs in association with autoimmune polyglandular syndromes (Chapter 212), either in childhood (type 1), in association with hypoparathyroidism and mucocutaneous candidiasis, or in adulthood (type 2), in association with insulin-dependent diabetes mellitus, autoimmune thyroid disease, alopecia areata, or vitiligo.

Adrenoleukodystrophy

Adrenoleukodystrophy, a rare (1 in 25,000) X-linked condition, is characterized by a deficiency of peroxisomal membrane adrenoleukodystrophy protein, which transports activated acyl-coenzyme A derivates into the peroxisomes, where they are shortened by β-oxidation. This deficiency results in the accumulation of very long chain fatty acids in the central nervous system and other tissues and increased plasma $C_{26:0}$ fatty acids. In the adrenal cortex, these very long chain fatty acids alter membrane function and inhibit signal transduction by ACTH. Incomplete penetrance of the genetic defect and variable accumulation of very long chain fatty acids in the adrenal gland, brain, testis, and liver account for the clinical phenotypes, which differ by age and presentation.[23]

Replacement of Adrenal Tissue

Infections cause about 15% of primary adrenal insufficiency. Typical infections include tuberculosis (Chapter 299) and systemic fungal diseases (e.g., histoplasmosis, coccidioidomycosis, blastomycosis [Chapter 308]), in which the adrenal tissue is replaced by caseating granulomas. End-stage AIDS-associated opportunistic infections, such as cytomegalovirus (Chapter 347) or *Mycobacterium avium-intracellulare* (Chapter 300), may reduce adrenal function. Adrenal tissue may be replaced by bilateral metastases (most commonly primary carcinoma of the lung, breast, kidney, or gut) or primary lymphoma, although adrenal insufficiency is uncommon. Intra-adrenal hemorrhage may also lead to insufficient steroidogenesis. Hemorrhage typically occurs in a stressed, hospitalized patient receiving long-term prophylactic anticoagulation and is often accompanied by back pain.

Congenital Adrenal Hyperplasias

The congenital adrenal hyperplasias[24] are a disparate group of diseases caused by a genetic deficiency of one of the enzymes needed for adrenal steroidogenesis. Patients with nearly complete deficiency of an enzyme required for cortisol synthesis present in infancy with adrenal insufficiency and salt-wasting crisis. This is most problematic in patients with mutation of the 21-hydroxylase (*CYP21A2*) or 11β-hydroxylase (*CYP11B1*) gene. The increase in ACTH levels caused by cortisol deficiency drives the intact steroidogenic pathways so that there is excessive production of the steroids just proximal to the enzymatic block—17-hydroxyprogesterone and 11-deoxycortisol, respectively, in 21-hydroxylase and 11β-hydroxylase deficiency. The increased levels of precursor steroids enable increased adrenal androgen synthesis, so that severely affected girls may be virilized in utero. Girls and women with nonclassic congenital adrenal hyperplasia present later; they have greater enzyme activity, so that cortisol production is adequate, but increased ACTH levels cause hyperandrogenism.

Rare Causes

Other rare causes of primary adrenal insufficiency (Table 208-5) include ACTH resistance, congenital adrenal hypoplasia, Smith-Lemli-Opitz syndrome (congenital cognitive impairment and multiple abnormalities owing to a deficiency in 7-dehydrocholesterol reductase), and amyloidosis (Chapter 174).

Secondary Adrenal Insufficiency

Suppression of the Pituitary Axis

Suppression of the hypothalamic-pituitary-adrenal axis by exogenous or endogenous glucocorticoids is the most common cause of secondary adrenal insufficiency. This phenomenon, which depends on the dose, duration, and schedule of glucocorticoid administration, becomes clinically manifest when glucocorticoid

TABLE 208-5 CAUSES OF ADRENAL INSUFFICIENCY AND ANCILLARY TESTS

SPECIFIC CAUSES	SUGGESTIVE CLINICAL FEATURES	USEFUL ANCILLARY TESTS
Primary adrenal insufficiency	Hyperpigmentation, orthostatic hypotension	Hyperkalemia, elevated ACTH
Idiopathic autoimmune destruction	Most common cause (80%) in developed countries; with or without other endocrinopathies, as below	Antibodies to 21-hydroxylase are present; on imaging, adrenal glands are small
Polyglandular failure type 1	Hypoparathyroidism, mucocutaneous candidiasis, vitiligo; age <20 years	
Polyglandular failure type 2	Insulin-dependent diabetes, autoimmune thyroid disease, alopecia areata, vitiligo; age >40 years	On imaging, adrenal glands are small
Infections: tuberculosis, systemic fungal diseases, AIDS-associated opportunistic infections (e.g., cytomegalovirus)	15% of patients in U.S. series	Adrenal glands tend to be large on CT and may be calcified
Space-occupying adrenal lesions	Metastases from carcinoma of lung, breast, kidney, gut; lymphoma or hemorrhage (heparin use)	Abnormal shape of adrenal glands on CT; evidence of hemorrhage
Bilateral adrenalectomy or treatment with steroidogenesis inhibitors		Ketoconazole, mitotane, aminoglutethimide, trilostane, and metyrapone reduce cortisol levels
Adrenoleukodystrophy	X-linked—screen males; in childhood, cognitive and gait disturbances; in adults, spastic paraparesis	Deficiency of peroxisomal very long chain acyl-coenzyme A synthetase leads to elevated plasma $C_{26:0}$ fatty acid levels
Secondary adrenal insufficiency		
Suppression of the adrenal axis by exogenous or endogenous glucocorticoids	Medication history; history of Cushing syndrome	Adrenal glands are small on imaging
Structural lesions of the hypothalamus or pituitary gland (tumors, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis)	Other pituitary deficiencies	Adrenal glands are normal or small on imaging; MRI or CT may show pituitary or hypothalamic lesion
Isolated ACTH deficiency		
Head trauma		

ACTH = adrenocorticotropic hormone; AIDS = acquired immunodeficiency syndrome; CT = computed tomography; MRI = magnetic resonance imaging.

treatment is stopped or when the patient is successfully treated with surgery. Adrenal suppression is unusual with "replacement" doses of glucocorticoid that are roughly equivalent to daily production (e.g., total daily doses of 15 to 20 mg hydrocortisone, 5 mg prednisone, or 0.3 to 0.5 mg dexamethasone). At higher doses, adrenal suppression is usually not seen until after 3 weeks of administration, and a single morning administration is less suppressive than are divided doses given during the day. This syndrome can be minimized by gradually tapering the glucocorticoid dose, so that the adrenal-pituitary axis can recover. Chronic opiate use may suppress pituitary ACTH secretion, but the frequency of frank adrenal insufficiency appears uncommon.[25]

Lesions of the Hypothalamus or Pituitary

Secondary adrenal insufficiency also may result from structural lesions of the hypothalamus or pituitary gland that interfere with CRH production or transport or with corticotrope function. These causes include tumors, trauma, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis (Chapters 204 and 205).

CLINICAL MANIFESTATIONS

The clinical presentation of adrenal insufficiency reflects the cause and duration of this uncommon condition. Primary adrenal insufficiency eventually destroys the entire adrenal cortex, with loss of both glucocorticoid and mineralocorticoid activity.

By contrast, secondary adrenal insufficiency reflects an inability of the hypothalamic-pituitary unit to deliver CRH or ACTH, thus reducing trophic support to otherwise normal glands. As a result, only cortisol production decreases because mineralocorticoid production is not very ACTH dependent (Fig. 208-7). Secondary adrenal insufficiency after the cessation of exogenous corticosteroids usually presents with fatigue, joint pain, and gastrointestinal symptoms (e.g., anorexia, nausea) within 48 hours, and the entire axis may not recover for up to 18 months.

The characteristic clinical presentation of acute primary adrenal insufficiency includes orthostatic hypotension, agitation, confusion, circulatory collapse, abdominal pain, and fever.[26,27] These features are most likely to be caused by hemorrhage, metastasis, or acute infection and can lead to death if not treated.

In chronic primary adrenal insufficiency, by contrast, the typical symptoms and signs include a longer history of malaise, fatigue, anorexia, weight loss, joint and back pain, and darkening of the skin (especially in the creases of the hands, extensor surfaces, recent scars, buccal and vaginal mucosa, and nipples). Patients may crave salt and may develop unusual food preferences, such as drinking the brine from pickles. Associated biochemical features for both acute and chronic presentations include hyponatremia, hypoglycemia, hyperkalemia, unexplained eosinophilia, and mild prerenal azotemia.

Chronic secondary adrenal insufficiency is manifested in a similar way, but without hyperpigmentation or mineralocorticoid abnormalities.

DIAGNOSIS

A morning serum cortisol measurement is an inexpensive but relatively insensitive screening test for adrenal insufficiency in patients who are not acutely ill. The diagnosis is virtually excluded by values greater than 18 μg/dL (about 500 nmol/L) when measured in immunoassays that have cross-reactivity with cortisol precursors. The diagnosis is likely if the value is less than 3 μg/dL (83 nmol/L), regardless of the assay.

However, both healthy individuals and patients with adrenal insufficiency may have indeterminate results (3 to 18 μg/dL) that require additional evaluation. In acute adrenal insufficiency, the serum cortisol value within a few hours of waking is generally inappropriately normal or subnormal in the setting of hypotension, in which cortisol values are usually well above 18 μg/dL.

Patients with acute adrenal insufficiency should be evaluated for sepsis, adrenal metastases, and hemorrhage. On MRI or CT imaging, the adrenal glands are small in autoimmune disease and large in cases of infection, metastatic disease, and adrenal hemorrhage. Imaging of the glands and other testing also may reveal an infectious or malignant cause.

For chronic adrenal insufficiency, the cortisol response to exogenous ACTH is a gold standard test. At any time of day, 250 μg of ACTH (1-24, cosyntropin) is given intravenously to provide a maximal stimulus to the adrenal gland; a serum cortisol level measured 30 and 60 minutes later should be greater than 18 μg/dL if measured by immunoassays that cross-react with cortisol precursors. When measured using more specific techniques (e.g., tandem mass spectrometry or monoclonal antibody-based immunoassay), the upper limit of normal is around 14 ug/dL.[28]

Values lower than these cutoffs indicate adrenal insufficiency. A 1-μg dose is equally good for establishing the diagnosis, if performed in the morning, but the difficulty in formulating a 1-ug dose increases the risk of a falsely normal result. A metyrapone stimulation test (a weight-based dose of metyrapone is given at midnight, cortisol and 11-deoxycortisol are measured the following morning) is useful in patients who have mild or recent secondary adrenal insufficiency and who may respond to pharmacologic doses of ACTH. Values of 11-deoxycortisol less than 7 ug/dL indicate adrenal insufficiency.

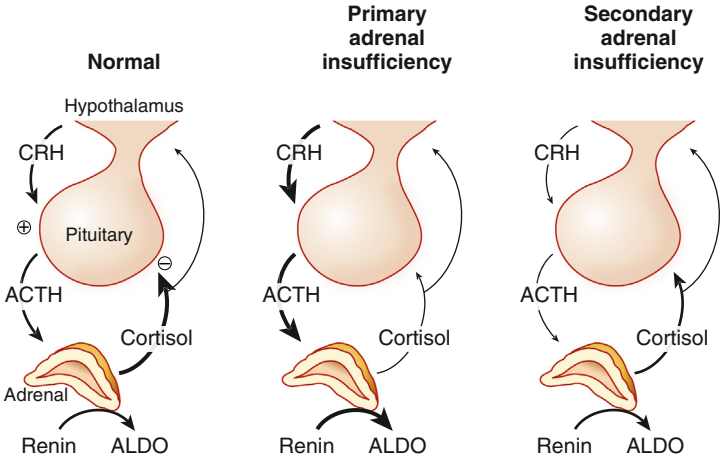

FIGURE 208-7. Physiology of the adrenal axis in health, primary adrenal insufficiency, and secondary adrenal insufficiency. ***In healthy individuals*** **(Normal), cortisol production is stimulated by the increased hypothalamic release of corticotropin-releasing hormone (CRH), which then travels down the pituitary stalk to stimulate adrenocorticotropic hormone (ACTH) secretion and release by corticotropes. Circulating ACTH stimulates adrenal gland production and secretion of cortisol. Cortisol then functions in a negative feedback mechanism to inhibit both CRH and ACTH.** ***In patients with primary adrenal insufficiency*****, destruction or replacement of the entire adrenal cortex results in decreased cortisol, aldosterone, and dehydroepiandrosterone (DHEA, not shown) secretion by the adrenal glands. As a result of decreased cortisol negative feedback, the normal hypothalamus and pituitary gland increase CRH and ACTH secretion. The decreased aldosterone levels lead to an increase in renin levels.** ***In patients with secondary adrenal insufficiency*** **(ALDO), ACTH or CRH secretion is reduced because of destruction or replacement of the hypothalamus or pituitary gland or because of disruption of the pituitary stalk. The decreased ACTH stimulation results in decreased cortisol (and, not shown, DHEA) secretion by the adrenal glands. Aldosterone production is only slightly affected by ACTH stimulation, and levels remain normal. The abnormal hypothalamus and pituitary gland do not increase CRH and ACTH secretion in response to the decreased cortisol negative feedback.**

Cerebral adrenoleukodystrophy, which presents in childhood, is characterized by cognitive and gait disturbances; the adult form, adrenomyeloneuropathy, is characterized by spinal cord and peripheral nerve demyelination. Because a substantial minority of patients in both groups present first with adrenal insufficiency, boys and young men with adrenal insufficiency should be screened for adrenoleukodystrophy.

Differential Diagnosis

Primary and secondary adrenal insufficiency can be distinguished by measurement of plasma ACTH. In primary adrenal insufficiency, ACTH levels are generally above the normal range and may exceed the normal range before the cortisol response to exogenous ACTH stimulation is subnormal. In addition, hyperkalemia and elevated renin values are characteristic of primary but not of secondary adrenal insufficiency, which is identified by a suppressed or inappropriately normal ACTH level.

Patients with primary adrenal insufficiency should undergo further evaluation to determine its cause. Detection of antibodies to 21-hydroxylase identifies nearly all patients with idiopathic disease. In a male with negative results, measurement of plasma $C_{26:0}$ fatty acids will detect adrenoleukodystrophy. Taken together, this strategy identifies the cause in nearly all adult patients with idiopathic adrenal insufficiency. Patients with autoimmune disease should be tested for other endocrine deficiencies, and those with adrenoleukodystrophy require neurologic evaluation.

Patients with secondary adrenal insufficiency not ascribed to glucocorticoid or opiate use should undergo imaging of the pituitary and hypothalamus to exclude a structural or infiltrating lesion as well as tests of other pituitary function to exclude additional deficiencies. In general, these are not reversible conditions.

TREATMENT

Acute Adrenal Insufficiency

In suspected acute adrenal insufficiency, hydrocortisone is the treatment of choice because it has both glucocorticoid and mineralocorticoid activity.[29] Treatment with intravenous saline for volume expansion, glucose for hypoglycemia, and intravenous hydrocortisone (100 mg) should be started immediately after placement of an intravenous line and withdrawal of blood for documentation of the cortisol value.[30]

Chronic Adrenal Insufficiency

Therapy for chronic adrenal insufficiency aims to provide the physiologic replacement of steroids. Glucocorticoid replacement is achieved by administration of 10 to 12 mg/m^2 of hydrocortisone daily in one to three oral doses, attempting to mimic the physiologic diurnal variation of cortisol concentrations. Hydrocortisone offers the advantage of multiple-dose tablets, which allow fine adjustment and splitting of the daily dose. Ideally, the morning dose is given as soon after waking as possible; for individuals who feel extremely fatigued in the morning before the agent is absorbed, a strategy of taking the medication 30 minutes before arising may be helpful. Some data suggest that once-daily dosing is preferable in terms of immune function, weight gain, and quality of life.[A3] Although many patients do well with a single dose, others complain of pronounced fatigue in the afternoon and evening. For these patients, a split-dose regimen, in which about one third of the daily dose is given around 4:00 PM or two afternoon doses are given, may be useful.

Other glucocorticoids may be used for daily replacement therapy. Prednisone, 4 to 7 mg daily, has the advantage of a long half-life and may be particularly helpful in patients with afternoon or evening fatigue. Dexamethasone is infrequently used because it is difficult to recommend a specific replacement dose and because few options are available for fixed doses.

Nearly all patients with primary adrenal insufficiency also require the mineralocorticoid fludrocortisone 50 to 300 μg/day. The dose is adjusted until plasma renin activity is normal. Patients should be encouraged to salt their food and not to limit salt intake. Some patients with primary adrenal insufficiency also have decreased serum DHEA levels, but evidence is insufficient to support its routine replacement.

Ensuring Proper Dosing

Education of the Patient

All patients receiving chronic glucocorticoid replacement therapy should be instructed that they must take the glucocorticoids as prescribed and that failure to take or to absorb the medication will lead to adrenal crisis and possibly death. Patients should wear a medical information bracelet or necklace. It is important to educate patients and their families about glucocorticoid adjustment during physiologic stress conditions, including the emergency administration of intramuscular glucocorticoid.

Dosing for Stress

Patients who are recovering from adrenal suppression caused by exogenous glucocorticoids should receive daily replacement glucocorticoid treatment and supplemental steroids at times of physiologic stress, depending on the degree of impairment, until the pituitary adrenal axis recovers, which may be weeks or months.[31,32] The daily oral glucocorticoid dose is usually doubled for "stressful" physiologic conditions, such as fever, nausea, and diarrhea, although this practice may lead to chronic overmedication by the patient because of a liberal interpretation of what constitutes physical stress. Thus education about when and how to change the dose of steroid should be reinforced periodically, preferably with written material, and the dangers of excessive steroid use should be emphasized. If the patient is vomiting, has severe diarrhea, or has collapsed, intramuscular glucocorticoids (e.g., 50 to 100 mg of hydrocortisone) should be given before transport to a medical facility.

The glucocorticoid dose is increased in proportion to the amount of stress. During maximally stressful situations (e.g., adrenal crisis, major surgery, trauma, labor and delivery), pharmacologic studies suggest that an initial intravenous hydrocortisone bolus of 50 to 100 mg followed by a continuous infusion of 200 mg over 24 hours is the best coverage.[33] The dose may be tapered by 50% per day if the patient is clinically stable. For more moderate stress, such as that of cholecystectomy, 75 to 100 mg of hydrocortisone is given on the day of surgery, and the dose is tapered more rapidly. Patients undergoing minimal stress, such as tooth extraction or short operative orthopedic procedures, may not require any additional supplementation.

Assessment to Ensure Proper Dosing

Clinical assessment is the best way to judge whether the glucocorticoid dose is correct. Symptoms of adrenal insufficiency improve with adequate therapy. The development of cushingoid features or osteopenia suggests frank or subtle overreplacement, respectively, and the presence of adrenal insufficiency symptoms (fatigue, anorexia, weight loss) suggests underreplacement. In women, DHEA replacement increases testosterone levels, so that hirsutism, acne, or other signs of androgen excess may suggest overreplacement.

In primary adrenal insufficiency, adequate hormone replacement results in plasma ACTH levels that decrease but remain elevated, in the range of 100 to 200 pg/mL. Renin values, however, normalize completely and may be used to judge the adequacy of mineralocorticoid replacement. Although hydrocortisone is cortisol, plasma cortisol values should not be used to monitor therapy because clearance from the bloodstream is rapid, and circulating values are low for most of the day.

PROGNOSIS

Even in educated patients with chronic adrenal insufficiency, adrenal crisis develops at a rate of 8.3 crises per 100 patient-years. Common precipitating causes include gastrointestinal infection, fever, and emotional stress (about 20% of cases each), but major pain, surgery, strenuous physical activity, heat, and pregnancy are other precipitants. About 6% of crises are fatal.

MINERALOCORTICOID DEFICIENCY

Hypoaldosteronism may be classified as a low-normal or a high renin state on the basis of plasma renin activity after 4 hours of upright posture. Renin deficiency, which is the most common cause of hypoaldosteronism, occurs most often in older patients with mild, nonoliguric renal disease who often have insulin-dependent diabetes and potentially diabetic nephropathy. Nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, other prostaglandin synthesis inhibitors, as well as autonomic dysfunction associated with prolonged bed rest can also result in hyporeninemic hypoaldosteronism.

CLINICAL MANIFESTATIONS

Few clinical features are associated with mineralocorticoid deficiency, so it is usually suspected when laboratory results reveal hyperkalemia, hyponatremia, and a mild metabolic alkalosis. If glucocorticoid deficiency is excluded, isolated hypoaldosteronism is established if the circulating level of aldosterone is inappropriately low.

High renin states of hypoaldosteronism include congenital adrenal hyperplasias with mineralocorticoid deficiency and primary adrenal insufficiency when it is treated with pure glucocorticoid replacement.

Treatment of these conditions involves sodium replacement with at least 10 mEq/kg/day, roughly equivalent to the 4 g of sodium chloride found in a typical diet in the United States. For individuals who do not maintain such a diet (often the elderly or the young), fludrocortisone can be given at the same doses used in primary adrenal insufficiency.

209 ADRENAL MEDULLA, CATECHOLAMINES, AND PHEOCHROMOCYTOMA

WILLIAM F. YOUNG, JR.

ADRENAL MEDULLA AND CATECHOLAMINES

The adrenal medulla occupies the central portion of the adrenal gland. Adrenomedullary cells are called chromaffin cells because they stain brown with chromium salts. Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia.[1] The largest cluster of chromaffin cells outside the adrenal medulla is near the level of the inferior mesenteric artery and is referred to as the organ of Zuckerkandl.

Catecholamines are substances that contain catechol (*o*-dihydroxybenzene) and a side chain with an amino group—the catechol nucleus (E-Fig. 209-1). Epinephrine, which is synthesized and stored in the adrenal medulla, is released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves.

Catecholamines have many cardiovascular and metabolic actions, including increasing the heart rate, blood pressure, myocardial contractility, and velocity of cardiac conduction. Three types of specific adrenergic receptors mediate their biologic actions: α, β, and DA. Their receptor subtypes are α_1, α_2, β_1, β_2, β_3, DA_1, and DA_2. The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increased blood pressure. The α_2-receptors are located on presynaptic sympathetic nerve endings and, when activated, inhibit the release of norepinephrine; stimulation causes suppression in central sympathetic outflow and decreased blood pressure. Stimulation of the β_1-receptor causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes, as well as bronchodilation, vasodilation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3-receptor regulates energy expenditure and lipolysis. DA_1 receptors are localized to the cerebral, renal, mesenteric, and coronary vasculature; stimulation causes vasodilation in these vascular beds. DA_2 receptors are presynaptic and localized to sympathetic nerve endings, sympathetic ganglia, and brain; their stimulation inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits the release of prolactin.

Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see E-Fig. 209-1). Tyrosine, which is derived from the diet or synthesized from phenylalanine in the liver, enters neurons and chromaffin cells by active transport. The conversion of tyrosine to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase is the rate-limiting step in the synthesis of catecholamines. α-Methyl-*p*-tyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting tumors. Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of dopa to dopamine. Dopamine is actively transported into granulated vesicles where it is hydroxylated to norepinephrine by the dopamine β-hydroxylase. These reactions occur in the synaptic vesicle of adrenergic neurons and the chromaffin cells of the adrenal medulla. In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where phenylethanolamine *N*-methyltransferase converts it to epinephrine. Expression of phenylethanolamine *N*-methyltransferase is positively regulated by glucocorticoids. Catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamine released is epinephrine.

The biologic half-life of circulating catecholamines is between 10 and 100 seconds, so plasma concentrations of catecholamines can fluctuate widely. Catecholamines are removed from the circulation by either reuptake by sympathetic nerve terminals or metabolism through two enzyme pathways (see E-Fig. 209-1), followed by sulfate conjugation and renal excretion. Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings (i.e., uptake 1). Uptake 1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazine. Extraneuronal tissues also take up catecholamines (i.e., uptake 2). Most of these catecholamines are metabolized by catechol-*O*-methyltransferase. Metanephrine and normetanephrine are oxidized by monoamine oxidase to vanillylmandelic acid by oxidative deamination. Monoamine oxidase may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. In the storage vesicle, norepinephrine is protected from metabolism by monoamine oxidase. Monoamine oxidase and catechol-*O*-methyltransferase metabolize dopamine to homovanillic acid (see E-Fig. 209-1).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

DEFINITION

Catecholamine-secreting tumors that arise from the chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas, respectively. Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both entities. However, the distinction between pheochromocytoma and paraganglioma is important because of differing risks for malignant transformation and different approaches to genetic testing for associated neoplasms.[2]

209 ADRENAL MEDULLA, CATECHOLAMINES, AND PHEOCHROMOCYTOMA

WILLIAM F. YOUNG, JR.

ADRENAL MEDULLA AND CATECHOLAMINES

The adrenal medulla occupies the central portion of the adrenal gland. Adrenomedullary cells are called chromaffin cells because they stain brown with chromium salts. Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia.[1] The largest cluster of chromaffin cells outside the adrenal medulla is near the level of the inferior mesenteric artery and is referred to as the organ of Zuckerkandl.

Catecholamines are substances that contain catechol (*o*-dihydroxybenzene) and a side chain with an amino group—the catechol nucleus (E-Fig. 209-1). Epinephrine, which is synthesized and stored in the adrenal medulla, is released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves.

Catecholamines have many cardiovascular and metabolic actions, including increasing the heart rate, blood pressure, myocardial contractility, and velocity of cardiac conduction. Three types of specific adrenergic receptors mediate their biologic actions: α, β, and DA. Their receptor subtypes are α_1, α_2, β_1, β_2, β_3, DA_1, and DA_2. The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increased blood pressure. The α_2-receptors are located on presynaptic sympathetic nerve endings and, when activated, inhibit the release of norepinephrine; stimulation causes suppression in central sympathetic outflow and decreased blood pressure. Stimulation of the β_1-receptor causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes, as well as bronchodilation, vasodilation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3-receptor regulates energy expenditure and lipolysis. DA_1 receptors are localized to the cerebral, renal, mesenteric, and coronary vasculature; stimulation causes vasodilation in these vascular beds. DA_2 receptors are presynaptic and localized to sympathetic nerve endings, sympathetic ganglia, and brain; their stimulation inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits the release of prolactin.

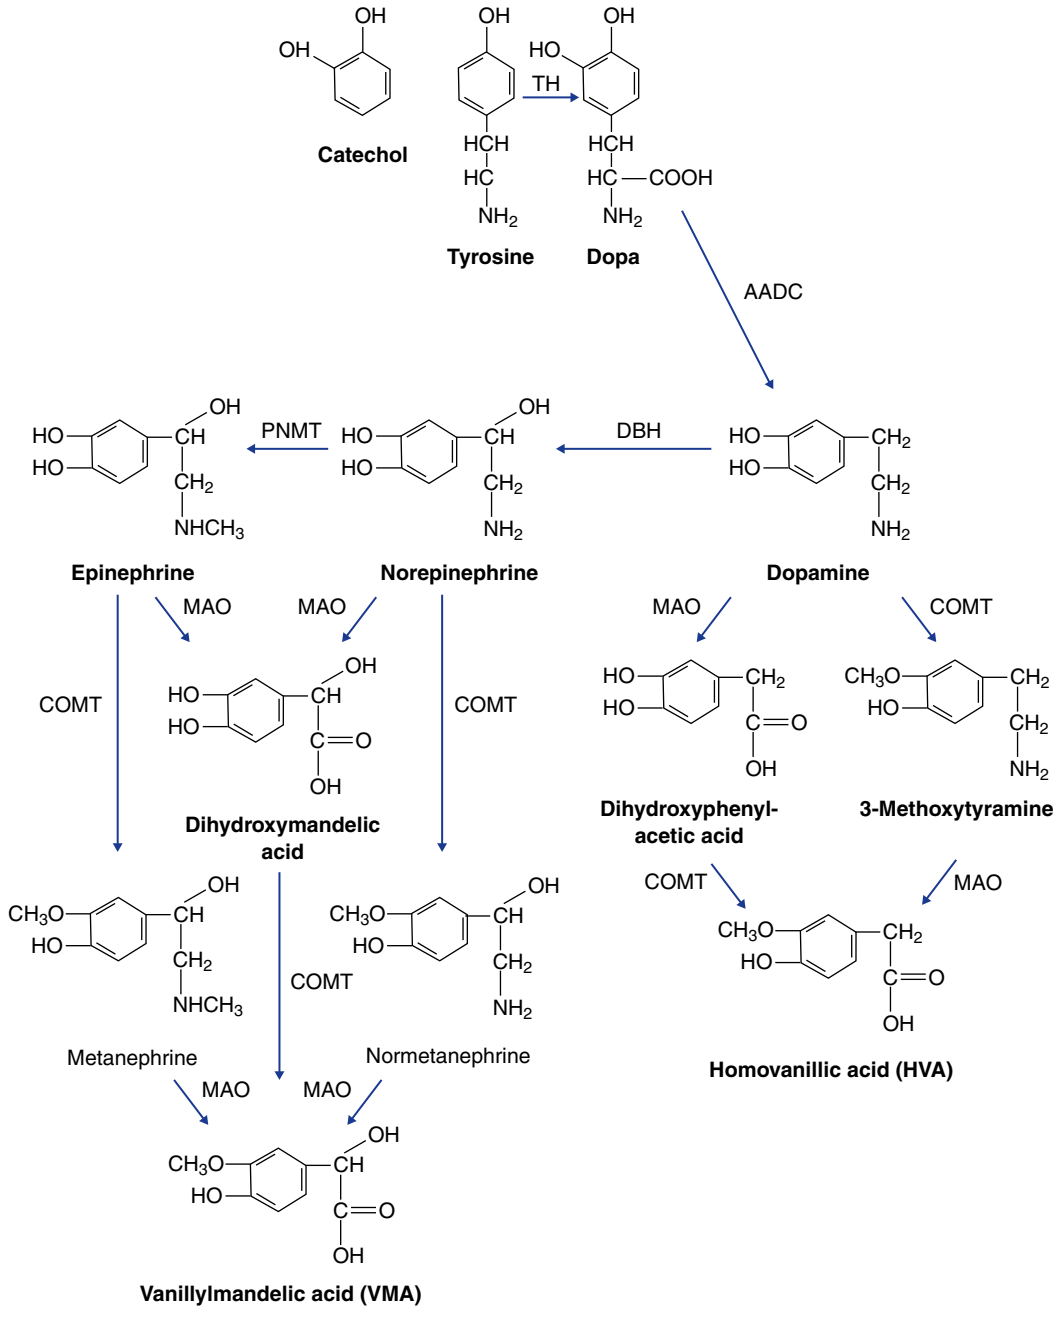
Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see E-Fig. 209-1). Tyrosine, which is derived from the diet or synthesized from phenylalanine in the liver, enters neurons and chromaffin cells by active transport. The conversion of tyrosine to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase is the rate-limiting step in the synthesis of catecholamines. α-Methyl-*p*-tyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting tumors. Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of dopa to dopamine. Dopamine is actively transported into granulated vesicles where it is hydroxylated to norepinephrine by the dopamine β-hydroxylase. These reactions occur in the synaptic vesicle of adrenergic neurons and the chromaffin cells of the adrenal medulla. In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where phenylethanolamine *N*-methyltransferase converts it to epinephrine. Expression of phenylethanolamine *N*-methyltransferase is positively regulated by glucocorticoids. Catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamine released is epinephrine.

The biologic half-life of circulating catecholamines is between 10 and 100 seconds, so plasma concentrations of catecholamines can fluctuate widely. Catecholamines are removed from the circulation by either reuptake by sympathetic nerve terminals or metabolism through two enzyme pathways (see E-Fig. 209-1), followed by sulfate conjugation and renal excretion. Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings (i.e., uptake 1). Uptake 1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazine. Extraneuronal tissues also take up catecholamines (i.e., uptake 2). Most of these catecholamines are metabolized by catechol-*O*-methyltransferase. Metanephrine and normetanephrine are oxidized by monoamine oxidase to vanillylmandelic acid by oxidative deamination. Monoamine oxidase may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. In the storage vesicle, norepinephrine is protected from metabolism by monoamine oxidase. Monoamine oxidase and catechol-*O*-methyltransferase metabolize dopamine to homovanillic acid (see E-Fig. 209-1).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

DEFINITION

Catecholamine-secreting tumors that arise from the chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas, respectively. Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both entities. However, the distinction between pheochromocytoma and paraganglioma is important because of differing risks for malignant transformation and different approaches to genetic testing for associated neoplasms.[2]



E-FIGURE 209-1. Biosynthetic and metabolic pathways for catecholamines. The term *catecholamine* comes from the catechol (*o*-dihydroxybenzene) structure and a side chain with an amino group—the catechol nucleus (*top left*). Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) in the rate-limiting step by tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT); cortisol serves as a cofactor for PNMT, and this is why epinephrine-secreting pheochromocytomas are almost exclusively localized to the adrenal medulla. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and norepinephrine to normetanephrine by meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid by oxidative deamination. Monoamine oxidase also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. Dopamine is also metabolized by monoamine oxidase and catechol-*O*-methyltransferase, with the final metabolite homovanillic acid.

ABSTRACT

Catecholamines, which affect many cardiovascular and metabolic processes, form the basis for many cardiovascular, pulmonary, and neuroendocrine pharmacotherapeutics. Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas, respectively. Although catecholamine-secreting tumors are rare, they are important to suspect, confirm, localize, and resect because of the risk of a lethal paroxysm, the likely cure of associated hypertension with surgical removal, and the ability to detect the 10% of tumors that are malignant. In addition, the detection of the 40% or so that are familial can accelerate diagnosis in other family members.

KEYWORDS

catecholamines
pheochromocytoma
paraganglioma

EPIDEMIOLOGY

Catecholamine-secreting tumors are rare, with an annual incidence of two to eight cases per million people. Over the past 3 decades, the diagnosed incidence of these tumors increased about five-fold because of smaller incidental tumors (adrenal incidentalomas; Chapter 208) detected on radiographic scans in patients with few or no symptoms.[3] Catecholamine-secreting tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades of life. These tumors are rare in children; when discovered, they may be multifocal, extra-adrenal, metastatic, and associated with a hereditary syndrome.[4]

PATHOBIOLOGY

Genetics

Approximately 40% of patients with catecholamine-secreting tumors have germline pathogenic variants (inherited mutations present in all cells of the body) in genes associated with the genetic disease.[5] Hereditary catecholamine-secreting tumors typically are manifested at a younger age than sporadic neoplasms. Sporadic pheochromocytoma is typically diagnosed on the basis of symptoms or incidental discovery on computed imaging,[6] whereas syndromic pheochromocytoma and paraganglioma are frequently diagnosed earlier in the course of disease because of biochemical surveillance or genetic testing.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) type 2A is an autosomal dominant disorder (Chapter 212). The phenotype includes adrenal pheochromocytoma in 50% (usually bilateral and sometimes asynchronous), medullary carcinoma of the thyroid in 100%, hyperparathyroidism in 20 to 30%, and cutaneous lichen amyloidosis in 5%. Medullary carcinoma of the thyroid is usually detected before the pheochromocytoma. Numerous activating pathogenic variants in the *RET* proto-oncogene have been documented in persons with MEN type 2A.

MEN type 2B, which is also an autosomal dominant disorder, represents approximately 5% of all MEN type 2 cases. The phenotype includes pheochromocytoma in 50% (usually bilateral), aggressive medullary carcinoma of the thyroid in 100%, mucosal neuromas (typically involving the tongue, lips, and eyelids) in most patients, thickened corneal nerves, intestinal ganglioneuromatosis, and marfanoid body habitus. MEN 2B–associated tumors are caused by pathogenic variants in the RET protein's intracellular domain, (see Chapter 212).

Von Hippel-Lindau Disease

Von Hippel-Lindau (VHL) disease (Chapter 385) is an autosomal dominant disorder in which nearly 100% of patients have an identifiable pathogenic variant in the VHL tumor suppressor gene.[7] Certain missense mutations appear to be associated with a "pheochromocytoma only" presentation. The disease is characterized by pheochromocytoma (frequently bilateral), paraganglioma (skull base, mediastinal, abdominal, pelvic), hemangioblastoma (involving the cerebellum, spinal cord, or brain stem), retinal angioma, clear cell renal cell carcinoma, pancreatic neuroendocrine tumor, endolymphatic sac tumor of the middle ear, serous cystadenoma of the pancreas, and papillary cystadenoma of the epididymis and broad ligament. Pheochromocytoma occurs in about 10 to 20% of patients with the disease.

Neurofibromatosis

Neurofibromatosis type 1 (Chapter 385) is an autosomal dominant disorder caused by inactivating pathogenic variants in the *NF1* tumor suppressor gene. It is characterized by neurofibromas, multiple café au lait spots, axillary and inguinal freckling, iris hamartomas (i.e., Lisch nodules), bone abnormalities, central nervous system gliomas, pheochromocytoma and paraganglioma, macrocephaly, and cognitive deficits. The expression of these features is variable. Approximately 3% of patients develop catecholamine-secreting tumors; in these patients, the tumor is usually a solitary benign adrenal pheochromocytoma, occasionally bilateral adrenal pheochromocytomas, and rarely an abdominal paraganglioma.

Familial Paraganglioma

Familial paraganglioma is an autosomal dominant disorder characterized by paragangliomas that are located in the skull base and neck, thorax, abdomen, and pelvis. Most cases of familial paraganglioma are caused by pathogenic variants in succinate dehydrogenase (succinate:ubiquinone oxidoreductase) subunit genes (*SDHB, SDHC, SDHD, SDHAF2, SDHA*), which compose portions of mitochondrial complex II. In patients with *SDHD* pathogenic variants, penetrance depends on the mutation's parent of origin: the disease does not manifest when the pathogenic variant is inherited from the mother but is highly penetrant when it is inherited from the father, a phenomenon known as maternal imprinting. Multiple cofactors are required for normal activity of the succinate dehydrogenase complex, including flavin adenine dinucleotide in the SDH1 subunit. Flavin adenine dinucleotide is covalently attached to the SDH1 subunit, and deletion of *SDHAF2* causes a complete loss of flavin adenine dinucleotide cofactor attachment (flavination) of the SDH1 subunit. As in families with pathogenic variants in *SDHD*, families with mutations in *SDHAF2* also exhibit maternal imprinting and parasympathetic paragangliomas that typically occur in the skull base and neck. Patients with *SDHB* pathogenic variants have an increased risk for malignant paraganglioma.

CLINICAL MANIFESTATIONS

Symptoms, when present, are due to the pharmacologic effects of excess concentrations of circulating catecholamines (Table 209-1). The typical hypertension may be sustained (in approximately half of patients) or paroxysmal (in approximately a third of patients), but about 15% of patients have normal blood pressure. Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation but usually include forceful heartbeat, pallor, tremor, headache, and diaphoresis. The spell may start with the sensation of a "rush" in the chest and a sense of shortness of breath, followed by a "pounding" heartbeat in the chest that typically progresses to a throbbing headache. Peripheral vasoconstriction with a spell results in cool or cold hands and feet as well as facial pallor. Increased sense of body heat and sweating are common toward the end of the spell. Spells may be spontaneous or be precipitated by postural change, anxiety, medications (e.g., metoclopramide, β-adrenergic inhibitors, anesthetic agents, corticosteroids), exercise, or maneuvers that increase intra-abdominal pressure (e.g., change in position, lifting, defecation, exercise, colonoscopy, pregnancy, trauma). Although the types of spells experienced by patients are highly variable, spells tend to be stereotypical for each patient. Spells may occur multiple times a day or as infrequently as once a month. The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may

TABLE 209-1 SIGNS AND SYMPTOMS ASSOCIATED WITH CATECHOLAMINE-SECRETING TUMORS

SPELL RELATED
Anxiety and fear of impending death
Diaphoresis
Dyspnea
Epigastric and chest pain
Headache
Hypertension
Nausea and vomiting
Pallor
Palpitation (forceful heartbeat)
Tremor
CHRONIC
Cold hands and feet
Constipation (megacolon)
Diaphoresis
Dyspnea
Ectopic hormone secretion–dependent symptoms (e.g., CRH/ACTH, GHRH, PTH-RP, VIP)
Epigastric and chest pain
Erythrocytosis
Fatigue
Fever
Headache
Heart failure—dilated or hypertrophic cardiomyopathy
Hyperglycemia
Hypertension
Livedo reticularis
Orthostatic hypotension
Painless hematuria (associated with urinary bladder paraganglioma)
Palpitation (forceful heartbeat)
Raynaud phenomenon
Retinopathy (grade II to IV)
Tremor
Weight loss
NOT TYPICAL OF PHEOCHROMOCYTOMA
Flushing

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; GHRH = growth hormone–releasing hormone; PTH-RP = parathyroid hormone–related peptide; VIP = vasoactive intestinal polypeptide.

Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab*. 1993;4:122-127.

be much shorter or persist for several hours. The clinician must recognize that most patients with such spells do not have a pheochromocytoma.

Fasting hyperglycemia and diabetes mellitus are caused in part by the α-adrenergic inhibition of insulin release.[8] Some of the cosecreted hormones that may dominate the clinical presentation include corticotropin (Cushing syndrome; Chapter 208), parathyroid hormone–related peptide (hypercalcemia; Chapter 227), vasopressin (syndrome of inappropriate antidiuretic hormone secretion; Chapter 101), vasoactive intestinal peptide (watery diarrhea; Chapter 126), and growth hormone–releasing hormone (acromegaly; Chapter 205) (see Table 209-1). Cardiomyopathy (Chapter 47) and heart failure are the symptomatic presentations of pheochromocytoma that are most frequently unrecognized by clinicians. Cardiomyopathy, whether dilated or hypertrophic, may be totally reversible with tumor resection. Some patients with pheochromocytoma may be asymptomatic despite high circulating levels of catecholamines, probably as a reflection or desensitization of adrenergic receptors owing to chronic stimulation.

DIAGNOSIS

Prompt diagnosis of these tumors is critical because of the risk of a lethal paroxysm, the ability to cure associated hypertension with surgical removal, the 10% chance that the tumor is malignant, and the 40% probability that the tumor is familial and may affect family members. Pheochromocytoma should be suspected in patients who have one or more of the following: hyperadrenergic spells (e.g., self-limited episodes of nonexertional palpitations, diaphoresis, headache, tremor, or pallor); resistant hypertension; a familial syndrome that predisposes to catecholamine-secreting tumors (e.g., multiple endocrine neoplasia type 2, neurofibromatosis type 1, Von Hippel-Lindau disease); a family history of pheochromocytoma or a history of a resected pheochromocytoma; a history of recurrent hypertension or spells; hypertension and diabetes; a pressor response during anesthesia, surgery, or angiography; onset of hypertension before age 20 years; and idiopathic dilated cardiomyopathy.

On a computed tomography (CT) scan, an incidentally discovered adrenal mass (Fig. 209-1) is more likely to be a pheochromocytoma if it shows precontrast attenuation greater than 10 Hounsfield units (HU), marked enhancement with intravenous contrast medium with slow contrast washout. By comparison, if the unenhanced CT attenuation value is 10 HU or less, the likelihood of pheochromocytoma is so low that further testing for pheochromocytoma is not necessary.[9] On magnetic resonance imaging (MRI), pheochromocytomas are characterized by low signal intensity on T1-weighted imaging and high signal intensity on T2-weighted imaging. Cystic and hemorrhagic changes, bilaterality, and large size (>4 cm) are typical findings.

FIGURE 209-1. Contrast-enhanced computed tomography of the abdomen in a 32-year-old second-year medical student with the peripartum discovery of a pheochromocytoma. The plasma fractionated metanephrines were abnormal: metanephrine, 0.19 nmol/L (normal, <0.5 nmol/L); normetanephrine, 28.6 nmol/L (normal, <0.9 nmol/L). The 24-hour urine values were abnormal: norepinephrine, 781 μg (normal, <170 μg); epinephrine, 2.4 μg (normal, <35 μg); dopamine, 197 μg (normal, <700 μg); metanephrine, 117 μg (normal, <400 μg); normetanephrine, 8760 μg (normal, <900 μg). The axial image shows a typical 5-cm heterogeneously enhancing right adrenal mass, consistent with pheochromocytoma (*arrow*). After α- and β-adrenergic blockade, a 5.3 × 5.0 × 2.0 cm, 40-g pheochromocytoma was removed laparoscopically.

Differential Diagnosis

Numerous disorders can cause signs and symptoms that may lead the clinician to test for pheochromocytoma. These disorders span much of medicine and include endocrine disorders (e.g., primary hypogonadism; Chapter 216), cardiovascular disorders (e.g., idiopathic orthostatic hypotension; Chapter 386), psychological disorders (e.g., panic disorder; Chapter 362), pharmacologic causes (e.g., withdrawal from an adrenergic inhibitor), neurologic disorders (e.g., postural orthostatic tachycardia syndrome; Chapter 388), and miscellaneous disorders (e.g., mast cell disease; Chapter 235). Indeed, most patients tested for pheochromocytoma do not have it. In addition, fractionated catecholamines and metanephrines may be elevated in several clinical scenarios: withdrawal from medications or drugs (e.g., clonidine, alcohol), any acute illness (e.g., subarachnoid hemorrhage, migraine headache, preeclampsia), and administration of many drugs and medications (e.g., tricyclic antidepressants, levodopa, cocaine, phencyclidine, lysergic acid diethylamide, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, isoproterenol) (Table 209-1).

Laboratory Findings

The diagnosis must be confirmed biochemically by increased concentrations of fractionated metanephrines in the plasma or fractionated catecholamines and metanephrines in a 24-hour urine collection (Fig. 209-2).[10] Measurement of plasma fractionated metanephrines is attractive because of its simplicity and high sensitivity (96 to 100%), but its specificity is only 85 to 89% and falls to 77% in patients older than age 60 years. Based on the low prevalence of pheochromocytoma, an estimated 97% of patients who have hypertension seen in a tertiary care practice and who have abnormal plasma fractionated metanephrine measurements do not have pheochromocytoma. As a result, if plasma levels are abnormal, the next step should be a reliable method of confirming a catecholamine-secreting tumor before embarking on expensive and time-consuming localization studies. The recommended approach is measurement of fractionated metanephrines and catecholamines in a 24-hour urine collection (sensitivity, 98%; specificity, 98%). Most laboratories now measure fractionated catecholamines (dopamine, norepinephrine, and epinephrine) and metanephrines (metanephrine and normetanephrine) by high-performance liquid chromatography with electrochemical detection or tandem mass spectroscopy.[11] These techniques have overcome the problems with fluorometric analysis (e.g., false-positive results caused by α-methyldopa, labetalol, sotalol, and imaging contrast agents).

Although it is preferable for patients not to receive any medications during the diagnostic evaluation, treatment with most medications can be continued. Tricyclic antidepressants interfere most frequently with the interpretation of fractionated catecholamines and metanephrines. For the effective detection of catecholamine-secreting tumors, treatment with tricyclic antidepressants and other psychoactive agents listed in Table 209-2 should be tapered and discontinued at least 2 weeks before any hormonal assessments. Furthermore, secretion of catecholamines may be appropriately increased in situations of physical stress or illness (e.g., stroke, myocardial infarction, congestive heart failure, obstructive sleep apnea).[12] Therefore, the clinical circumstances under which catecholamines and metanephrines are measured must be assessed in each case.

Localization of the Tumor(s)

Symptomatic pheochromocytomas are localized to the adrenal glands, with an average diameter of 4.5 cm (see Fig. 209-1). Paragangliomas are found where there is chromaffin tissue: along the para-aortic sympathetic chain, within the organs of Zuckerkandl (at the origin of the inferior mesenteric artery), in the wall of the urinary bladder, and along the sympathetic chain in the neck or mediastinum. Paragangliomas in the skull base and neck region (e.g., carotid body tumors, glomus tumors, chemodectomas) usually arise from parasympathetic tissue and typically do not hypersecrete catecholamines and metanephrines, whereas paragangliomas in the mediastinum, abdomen, and pelvis usually arise from sympathetic chromaffin tissue and usually do hypersecrete catecholamines and metanephrines.

Localization studies should not be initiated until biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor (see Fig. 209-2). Computer-assisted imaging of the adrenal glands and abdomen with CT or MRI should be the first localization test (sensitivity, >95%; specificity, >65%). Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen and pelvis. If the results of abdominal imaging are normal, localization with gallium 68 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-octreotate positron emission tomography (68-Ga DOTATATE PET) is indicated (see Fig. 209-2). Ga-68 DOTATATE PET CT has a lesion-based detection rate of 96-98% and is superior to ^{123}I

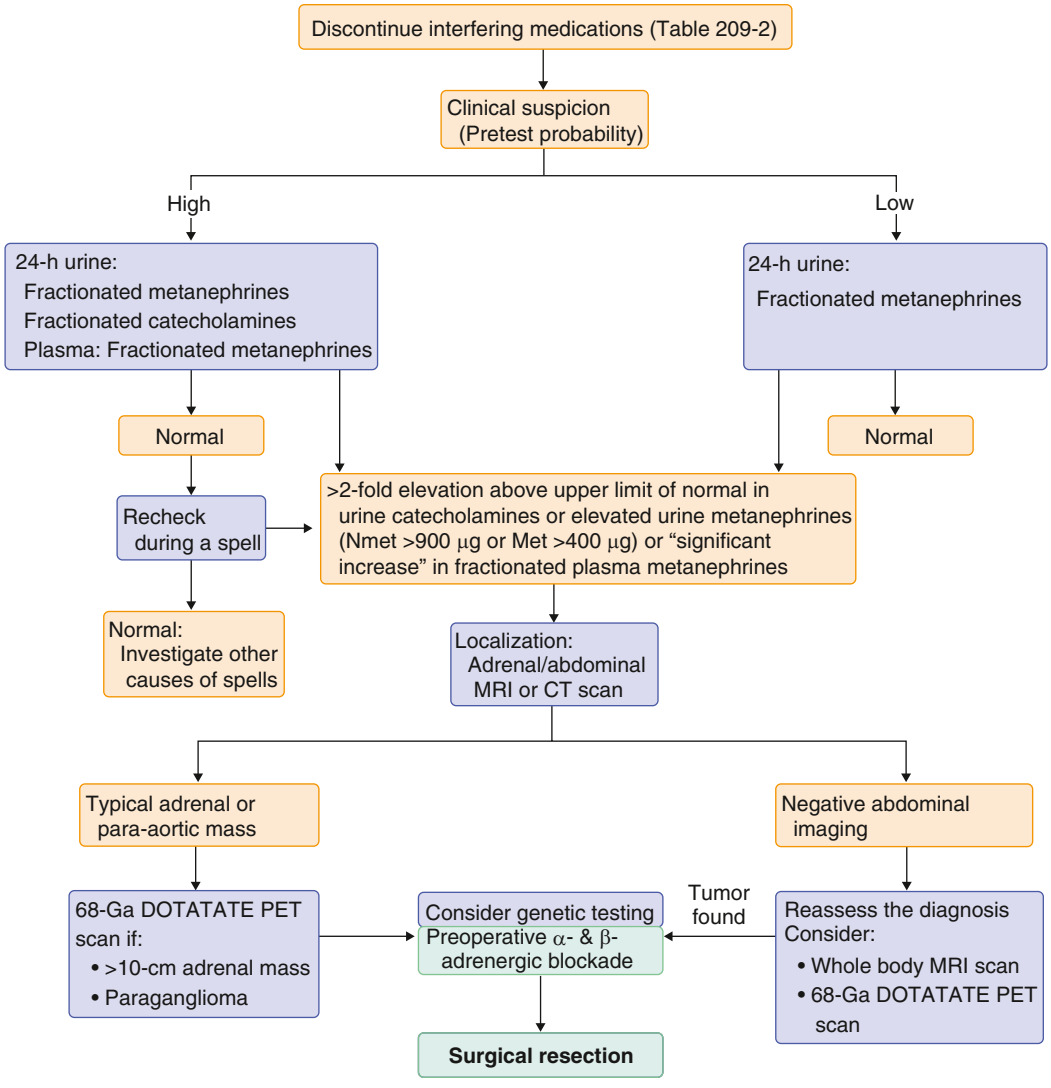


FIGURE 209-2. Evaluation and treatment of catecholamine-secreting tumors. Clinical suspicion is triggered by the following: paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; family history of pheochromocytoma or associated conditions; or incidentally discovered adrenal mass. The details are discussed in the text. CT = computed tomography; Ga-68 DOTATATE = gallium 68 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-octreotate; Met = metanephrine; MRI = magnetic resonance imaging; Nmet = normetanephrine; PET = positron emission tomography. (Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab*. 1993;4:122-127.)

TABLE 209-2 MEDICATIONS THAT MAY INCREASE MEASURED LEVELS OF CATECHOLAMINES AND METANEPHRINES

Tricyclic antidepressants (including cyclobenzaprine)
Levodopa
Drugs containing adrenergic receptor agonists (e.g., decongestants)
Amphetamines
Buspirone and antipsychotic agents
Monoamine oxidase inhibitors (MAO inhibitors)
Prochlorperazine
Reserpine
Serotonin and norepinephrine reuptake inhibitors (SNRIs)
Withdrawal from clonidine and other drugs
Ethanol

metaiodobenzyl guanidine (^{123}I-MIBG) scintigraphy.[13] If a typical (<10 cm) unilateral adrenal pheochromocytoma is found on CT or MRI, Ga-68 DOTATATE PET CT or MIBG is superfluous. If the adrenal pheochromocytoma is larger than 10 cm in diameter or if a paraganglioma is identified on CT or MRI, Ga-68 DOTATATE PET CT or ^{123}I-MIBG scintigraphy is indicated because the patient has an increased risk of malignant disease and additional paragangliomas. Ga-68 DOTATATE and ^{18}F-fluorodeoxyglucose positron emission tomography are excellent imaging modalities to detect metastatic disease.

Other localizing procedures that can be used but are rarely required include computer-assisted imaging of the chest, skull base, and neck (see Fig. 209-2). Because of marked gradients between the adrenal glands in nonpheochromocytoma patients, adrenal venous sampling for catecholamines is not helpful in the investigation of adrenal pheochromocytoma.

Genetic Testing

Genetic testing in clinically approved molecular genetic diagnostic laboratories (see https://www.ncbi.nlm.nih.gov/gtr/) should be considered in all patients with paraganglioma or pheochromocytoma. Genetic counseling is recommended prior to testing to help families understand the implications of genetic test results, to coordinate the testing of at-risk individuals, and to help families work through the psychosocial issues that may arise before, during, or after the testing process.[14]

More than 15 different pheochromocytoma and paraganglioma susceptibility genes have been reported: *NF1, RET, VHL, SDHD, SDHC, SDHB, EGLN1/PHD2, KIF1B, SDHAF2, IDH1, TMEM127, SDHA, MAX, HIF2A*, and *FH* gene encoding fumarate hydratase. The risk of familial disease is highest if a patient has one or more of the following: paraganglioma, bilateral adrenal pheochromocytomas, unilateral adrenal pheochromocytoma with a family history of pheochromocytoma or paraganglioma, onset of unilateral adrenal pheochromocytoma before age 45 years, or clinical findings suggestive of one of the previously discussed syndromic disorders.[15,16]

TREATMENT

Medical Therapy

Some form of preoperative pharmacologic preparation is indicated for all patients who have catecholamine-secreting neoplasms.[17] Combined α- and β-adrenergic blockade is one approach to control blood pressure and to prevent intraoperative hypertensive crises.[18] α-Adrenergic blockade should be started 7 to 10 days preoperatively to normalize blood pressure and to expand the contracted blood volume. A longer duration of preoperative α-adrenergic blockade is indicated in patients with recent myocardial infarction, catecholamine cardiomyopathy, or catecholamine-induced vasculitis. Blood pressure should be monitored with the patient in the seated and standing positions twice daily. Target blood pressure is less than 120/80 mm Hg (seated), with systolic blood pressure greater than 90 mm Hg (standing); both targets should be modified on the basis of the patient's age and comorbid disease. On the second or third day of α-adrenergic blockade, patients are encouraged to start a diet high in sodium (≥5000 mg daily) because of the catecholamine-induced volume contraction and the orthostasis associated with α-adrenergic blockade. This degree of volume expansion may be contraindicated in patients with heart failure or renal insufficiency. After adequate α-adrenergic blockade has been achieved, β-adrenergic blockade is initiated if the average heart rate is greater than 80 beats per minute.

Phenoxybenzamine, which is the preferred drug to control blood pressure and arrhythmia preoperatively, is an irreversible, long-acting, nonspecific α-adrenergic blocking agent. The initial dosage is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg in divided doses every 2 or 3 days as needed to control blood pressure and spells. The final dosage of phenoxybenzamine is typically between 20 and 100 mg daily. The more selective α-adrenergic blocking agent doxazosin (with a starting dose of 1 mg at bedtime) appears to be about equally effective in terms of surgical safety[A1] and is increasingly being used instead of phenoxybenzamine.[19]

A β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective, because β-adrenergic blockade alone may make hypertension more severe owing to unopposed α-adrenergic stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. The clinician should exercise caution if the patient has asthma or heart failure. Chronic catecholamine excess can produce a cardiomyopathy that may become evident with the initiation of β-adrenergic blockade, thereby resulting in acute pulmonary edema. Therefore, the β-adrenergic blocker (e.g., extended-release metoprolol, 25 mg once daily) should be administered cautiously and at a low dose. Other agents that may be used to prepare the patient with pheochromocytoma for surgery include α-methyl-*p*-tyrosine (metyrosine)[20] (starting at 250 mg every 6 hours) and amlodipine (titrated as high as 20 mg daily).[A2] Despite treatment, patients with pheochromocytomas have more perioperative hemodynamic instability than nonpheochromocytoma patients undergoing adrenal surgery. Acute hypertensive crises may occur before or during an operation, and they should be treated with intravenous sodium nitroprusside, phentolamine, or nicardipine (Chapter 64). Unlike other causes of hypertensive crisis, however, β-adrenergic blockers should be avoided.

Surgical Therapy

The treatment of choice for pheochromocytoma is complete surgical resection. Surgical survival rates are 98 to 100% and are highly dependent on the skill of the endocrinologist–endocrine surgeon–anesthesiologist team. Careful preoperative pharmacologic preparation with either phenoxybenzamine or doxazosin is crucial for successful treatment. Most catecholamine-secreting tumors are benign and can be totally excised. Tumor excision usually cures hypertension.

The laparoscopic approach to the adrenal gland is the procedure of choice for a solitary intra-adrenal pheochromocytoma smaller than 8 cm in diameter. Surgical expertise is key to avoid intraoperative tumor capsule rupture. Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy in cases of difficult dissection, invasion, adhesions, or an inexperienced surgeon. An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches.

Management of Complications

Hypotension may occur during and after surgical resection of the pheochromocytoma, and it should be treated with fluids and colloids and then intravenous pressor agents if necessary. Postoperative hypotension is less frequent in patients who have had adequate preoperative α-adrenergic blockade and volume expansion. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered as a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored, and intravenous fluids should contain 5% dextrose.

PROGNOSIS

Approximately 1 to 2 weeks after surgery, fractionated catecholamines and metanephrines should be measured by collection of a 24-hour urine specimen. If the levels are normal, resection of the pheochromocytoma should be considered complete. Increased levels of fractionated catecholamines and metanephrines detected postoperatively are consistent with residual tumor owing to either a second primary lesion or occult metastases.

About 3% of pheochromocytomas recur within 6 years after what is thought to be curative surgery.[21] The 24-hour urinary excretion of fractionated catecholamines and metanephrines or plasma fractionated metanephrines should be checked annually, perhaps for life. Annual biochemical testing assesses for metastatic disease, tumor recurrence in the adrenal bed, or delayed appearance of multiple primary tumors. Follow-up CT or MRI is not needed unless the metanephrine or catecholamine levels become elevated or the original tumor was associated with minimal or no catecholamine or metanephrine excess.

METASTATIC PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Distinguishing between benign and malignant catecholamine-secreting tumors is difficult on the basis of clinical, biochemical, or histopathologic characteristics. As a result, the diagnosis of malignancy is based on documentation of metastatic disease (e.g., lymph nodes, bone, lung, liver). Metastases develop at a median of 5.5 years (range, 0.3 to 53.4 years) after the initial diagnosis. There is no cure for metastatic pheochromocytoma and paraganglioma.

The clinician should assess the pace of the malignant disease and base the level of therapy on the aggressiveness of the tumor's behavior. A multimodality, multidisciplinary, individualized approach is indicated to control catecholamine-dependent symptoms, local mass effects, and overall tumor burden.[22] Metastatic lesions should be resected, if possible, to decrease the burden of tumor. Skeletal metastatic lesions that are painful or threaten structural function can be treated with external radiotherapy or thermal ablation, or they can be approached surgically. Thermal ablation may also be used to treat small (e.g., ≤3 cm in diameter) liver metastases. External radiotherapy can also be used to treat unresectable soft tissue lesions. In selected cases, long-acting octreotide has been beneficial under expert care. If the metastatic disease is considered aggressive and the tumor burden has exceeded that which can be managed with targeted treatment options (such as sunitinib under expert oversight),[23] cytotoxic chemotherapy with cyclophosphamide, vincristine, and dacarbazine under expert care can stabilize the disease. If cytotoxic chemotherapy proves ineffective, treatment can be guided by molecular imaging, with 177Lu-DOTATATE or 131I-MIBG, depending on which method showed the best expression on imaging.[24]

Median overall and disease-specific survivals are 24.6 and 33.7 years, respectively. However, 13% of patients die within 5 years of diagnosis, and shorter survival correlates with male sex, older age at the time of primary tumor detection, synchronous metastases, larger primary tumor size, elevated dopamine, and not undergoing primary tumor resection.

PHEOCHROMOCYTOMA IN PREGNANCY

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother. In one series, the diagnosis was made before pregnancy in 15% of pregnancies, during pregnancy in 55%, and after delivery in 30%.[25] The approach to the biochemical diagnosis is the same as for nonpregnant patients. MRI without gadolinium enhancement is the preferred imaging modality. ^{123}I-MIBG scintigraphy and Ga-68 DOTATATE PET-CT are contraindicated.

The treatment of hypertensive crises is the same as for nonpregnant patients, except that nitroprusside should be avoided. The preoperative preparation is the same as for nonpregnant patients.

Adverse outcomes are associated with unrecognized pheochromocytoma during pregnancy, tumors in the abdominal or pelvic areas, and catecholamine excess at least 10 times the upper limit of the normal range. For patients who are diagnosed during pregnancy, α-adrenergic blockade therapy has been associated with fewer adverse outcomes, whereas surgery during pregnancy has not been associated with better outcomes.

210 DIABETES MELLITUS

KETAN K. DHATARIYA, GUILLERMO E. UMPIERREZ, AND JILL P. CRANDALL

OVERVIEW

Diabetes mellitus is a chronic metabolic disorder characterized by raised glucose concentrations and associated alterations in the metabolism of fat, protein, and carbohydrates. Chronically elevated blood glucose levels increase the risk of developing macrovascular and microvascular complications. Diabetes comprises a cluster of heterogeneous disorders with elevated blood glucose concentrations, but the cluster includes many subcategories, each of which requires tailored prevention, diagnosis, and treatment approaches. Genetic factors may predispose or protect individuals from the deleterious effects of chronic hyperglycemia.

Depending on the context in which the patient presents, diabetes can be an acute life-threatening condition, a pregnancy-associated disorder, or a gradually evolving chronic disorder that, over many years, carries the potential for causing life-limiting complications. Diabetes-related microvascular and macrovascular complications stem from chronic suboptimal control of the metabolic disturbances—defined principally by the hyperglycemia. The risk of developing these complications can be significantly reduced by early and aggressive maintenance of near-physiologic blood glucose concentrations.

The management of diabetes can be challenging because of its varying presentations across the age spectrum, the requirement that the person with diabetes must actively participate in their own treatment, and the evolving clinical manifestations in the same patient. Because the severity of the underlying metabolic defects does not remain static, management almost always requires changes as the disease progresses. The management of diabetes can be especially challenging in vulnerable populations with limited resources or access to appropriate medical care (Chapter 4).

DEFINITION

The definition of the different types of diabetes is based on their etiology and pathogenesis (Table 210-1). Type 1 diabetes, which is caused by an autoimmune destruction of the β cells of the pancreatic islets of Langerhans, accounts for between 5% and 10% of all forms of diabetes. Type 1 diabetes should not be called "juvenile-onset diabetes," because its onset can be at any age, and is no longer termed "insulin-dependent diabetes," even though insulin is usually required from the time of diagnosis, because type 2 diabetes also may require insulin therapy.

Type 2 diabetes, which accounts for over 90% of all forms of diabetes, is characterized by impaired insulin secretion and insulin action. It should not be called "adult-onset diabetes," because it is increasingly being diagnosed in the growing number of obese children and teenagers. It also should not be called "non–insulin-dependent diabetes" because some patients require insulin therapy when a combination of lifestyle change (i.e., diet and exercise) and oral or noninsulin injectable medications are insufficient.

Gestational diabetes (Chapter 221) can develop during pregnancy in women who do not have a previous diagnosis of diabetes. About 2 to 10% of pregnant women are affected, but its incidence has been rising with the increased prevalence of obesity. Gestational diabetes usually is the result of impaired glucose tolerance owing to dysfunction of pancreatic β cells as well as impaired insulin action (insulin resistance). Gestational diabetes usually resolves at delivery, but affected women have up to a 60% lifetime risk of progressing to type 2 diabetes.

Diabetes also can be caused by diseases of the exocrine pancreas, including (but not limited to) pancreatitis (Chapter 130), trauma, cystic fibrosis (Chapter 77), neoplastic disease (Chapter 180), new-onset diabetes after transplantation, and iron deposition in hemochromatosis (Chapter 196). The presence of excessive counter-regulatory hormones, for example, Cushing syndrome (Chapter 208), acromegaly (Chapter 205), glucagonoma (Chapter 213), and pheochromocytoma (Chapter 209), can induce insulin resistance and cause type 2 diabetes. Hyperglycemia also may be associated with the use of certain drugs, including drugs that worsen insulin resistance (e.g., glucocorticoids, nicotinic acid, thiazide diuretics) and those that impair β-cell function (e.g., pentamidine, diazoxide, interferon gamma). Chemotherapeutic agents, in particular the immune checkpoint inhibitors, can also induce type 1 or type 2 diabetes.[1] Monogenic defects include neonatal diabetes and maturity-onset diabetes of the young (see Pathobiology).

In the United States, about 34 million adults over age 18 years have diabetes, thereby resulting in a prevalence of about 13 to 14%, about 95% of which is type 2. About 0.7% of U.S. adults are newly diagnosed with diabetes each year. Before the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, diabetes was the seventh leading cause of death, accounting for nearly 90,000 deaths each year. Worldwide, the numbers are staggering. Over 500 million adults have diabetes, representing a prevalence of about 10%, and about 75% of affected individuals are in low- and middle-income countries.

TABLE 210-1 THE DIFFERENCES BETWEEN TYPE 1 AND TYPE 2 DIABETES

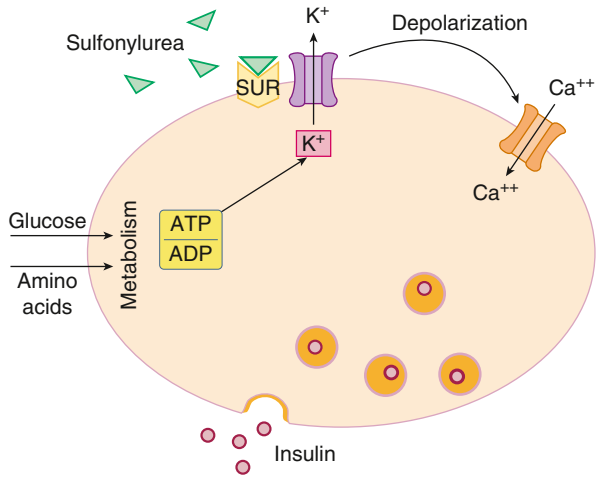
	TYPE 1	TYPE 2
Age at onset	Childhood or early adulthood, but can be manifested at any age	Middle age or older adults, but can be present in obese children and adolescents
Family history/genetic factors	Genetic risk defined, but most cases are sporadic	Strong genetic component, polygenic in most cases
Environmental triggers	Largely unknown	Obesity, sedentary lifestyle
Requirement for insulin therapy	Universal	Variable
Frequency among people with diabetes	5-10%	≈90%
Associated disorders	Autoimmunity and endocrine disorders (especially thyroid)	Obesity, hypertension, dyslipidemia, polycystic ovary syndrome

PATHOBIOLOGY

Maintenance of a constant blood glucose concentration is essential for normal physiology and particularly for the central nervous system, because the brain can neither synthesize nor store the amount of glucose required for its normal function. A normal blood glucose concentration requires a balance between the endogenous glucose production by the liver and kidneys and the utilization of glucose by peripheral tissues. Insulin, which is the main glucoregulatory hormone, inhibits the hepatic production of glucose and stimulates the uptake of peripheral glucose.

Insulin is initially synthesized as preproinsulin in the ribosomes of the rough endoplasmic reticulum of pancreatic islet β cells. It is then modified post-translationally to proinsulin, which in turn is transported to the Golgi apparatus, where it is packaged into secretory granules. Proinsulin is post-translationally modified by cleavage into equimolar concentrations of insulin and a connecting segment (C-peptide) in the secretory granules. A rise in the plasma glucose level results in the stimulation of insulin secretion and the release of equimolar quantities of insulin and C-peptide (as well as a small amount of proinsulin) into the hepatic portal vein. A large proportion of insulin is bound to its hepatic receptor and metabolized during its "first pass" through the liver. C-peptide, by comparison, is much less prone to hepatic metabolism, is a better reflection of insulin secretion, and therefore is useful as a biomarker to quantify insulin secretion. However, C-peptide itself is of limited usefulness in the clinical diagnosis or treatment of diabetes (Fig. 210-1).

The principal regulator of insulin secretion is glucose (E-Fig. 210-1). Glucose is taken up by the β cells through the GLUT2 glucose transporter system and then phosphorylated to glucose 6-phosphate by an islet-specific glucokinase. Glucokinase can be considered the "glucose sensor" of the β cell, and mutations in this enzyme lead to type 2 maturity-onset diabetes of the young. The conversion of glucose to glucose 6-phosphate results in a sequential increase in intracellular adenosine triphosphate (ATP) and closing of the ATP-dependent potassium (K_{ATP}) channels in the β-cell membrane. The K_{ATP} channel is usually open in the fasting state and is made up of the sulfonylurea 1 receptor (SUR1) and an inward potassium channel subunit, Kir6.2. Rising ATP concentrations lead to the closure of the K_{ATP} channel, thereby resulting in membrane depolarization and the influx of calcium. The calcium binds to calmodulin, which activates myosin light-chain kinase, which



E-FIGURE 210-1. Nutrient regulation of insulin secretion. Glucose is taken up by the β cell by the GLUT2 glucose transporter and is metabolized initially by phosphorylation by glucokinase to glucose 6-phosphate. The rise in glucose 6-phosphate leads to an increase in intracellular ATP and an increase in the cytoplasmic ATP/ADP ratio, which causes closure of the ATP-dependent potassium channel (K_{ATP}), followed by membrane depolarization and the subsequent opening of voltage-gated calcium channels. The influx of calcium mobilizes the insulin secretory granules to fuse with the cell membrane and to release insulin into the extracellular fluid. The sulfonylurea 1 receptor (SUR1) is a component of the ATP-dependent potassium channel. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

ABSTRACT

Diabetes mellitus is a common chronic metabolic disorder that is characterized by elevated blood glucose concentrations. The two main types are type 1 diabetes, in which autoimmune destruction of the pancreatic β cells results in a deficiency of insulin, and type 2 diabetes, which is caused by the impaired secretion and action of insulin. Other causes of diabetes include but are not limited to pancreatic disease, pregnancy, drug-induced diabetes, or genetic defects. Chronic hyperglycemia is associated with microvascular complications, including retinopathy, nephropathy, and neuropathy, as well as macrovascular complications, including coronary artery disease, peripheral vascular disease, and stroke. The treatment of type 1 diabetes requires that insulin be replaced and is helped by dietary modification. For type 2 diabetes, treatments include dietary modification, exercise, weight management, and medication. The pharmacologic options for type 2 diabetes include an array of oral and injectable medications, often used in combination. Aggressive control of hyperglycemia and optimization of other modifiable risk factors for microvascular and macrovascular disease can substantially reduce the risk of developing the complications of chronic diabetes. Acute, life-threatening diabetic complications include iatrogenic hypoglycemia, diabetic ketoacidosis, and the hyperglycemic hyperosmolar state. Newer pharmacologic agents and therapeutic options (e.g., continuous glucose monitoring and insulin infusion) have improved the control of glycemic levels and quality of life for many people who are living with diabetes.

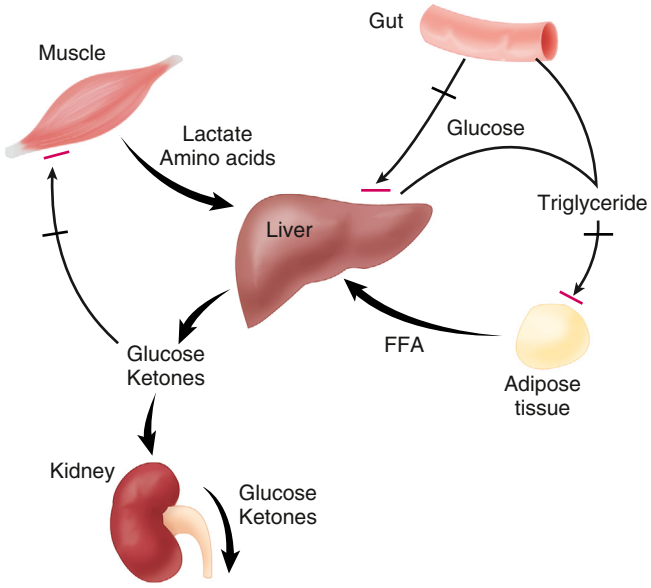

FIGURE 210-1. Effects of insulin deficiency on the metabolism of body fuel. A lack of insulin leads to a lack of cellular uptake of glucose, thereby necessitating mobilization of alternative substrates for gluconeogenesis and ketogenesis. These substrates come from amino acids in muscle and free fatty acids released from adipose tissue. These precursors are metabolized in the liver to form glucose and ketones. The impaired removal of endogenous and exogenous metabolic fuels by insulin-responsive tissues leads to worsening hyperglycemia and hyperketonemia that overwhelm renal removal mechanisms. The result is symptomatic hyperglycemia, with polyuria (and subsequent polydipsia) owing to the osmotic diuresis of glycosuria and ketonuria, as well as weight loss owing to the breakdown of muscle and adipose tissue and the loss of glucose and ketones in the urine. Genital mycotic infections can be precipitated by the presence of glucose in the urine. FFA = free fatty acids.

leads to the migration of the insulin secretory granules to the cell membrane, which fuse together to allow exocytosis of insulin into the extracellular fluid. Mutations in either the SUR1 gene or the Kir6.2 gene can lead to loss of K_{ATP} activity; as a result, the cell is continuously depolarized, thereby resulting in the chronic release of insulin and a syndrome termed "persistent hyperinsulinemic hypoglycemia of infancy." Mutations in Kir6.2 and SUR1 have also been identified in infants with permanent neonatal diabetes mellitus. Because sulfonylureas bind to the SUR1 receptor and cause insulin release, treatment with these agents can normalize insulin secretion and glucose concentrations in people with this condition.

The magnitude of the insulin secretory response is determined by the blood glucose concentration as well as by the rate and mode of glucose entry. Compared with the intravenous administration of glucose, greater amounts of insulin are produced when glucose is taken orally because of the simultaneous release of the gut-derived hormones known as incretins. These incretins include glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), both of which augment insulin secretion. Rapid increases in the blood glucose concentration (e.g., after intravenous administration of glucose) cause a spike of insulin secretion that peaks within a few minutes and declines quickly (so-called first-phase insulin secretion). With more persistent elevations of the plasma glucose concentration, insulin secretion is sustained (so-called second-phase insulin secretion). The earliest pathophysiologic indicator of defective β-cell function may be the loss of first-phase secretion of insulin, which precedes by years the decline in insulin secretory reserve sufficient to lead to overt glucose intolerance or diabetes.

Another abnormality in type 2 diabetes is the blunted secretion of these incretin hormones after the oral administration of carbohydrate. Drugs are now available to mimic or enhance this incretin effect (see Treatment of type 2 diabetes).

The actions of insulin on its principal target organs (i.e., muscle, fat, liver) are mediated by its interaction with the insulin receptor and have complex and coordinated effects on the metabolism of carbohydrates, proteins, and lipids (see Fig. 210-1). Insulin receptor signaling through insulin receptor substrate 1 and phosphatidylinositol 3-kinase is a major pathway in the mediation of insulin-stimulated glucose transport, notably by stimulating the translocation of the glucose transporter GLUT4 to the cell membrane. This pathway is also responsible for the vasodilator effects of insulin on large vessels and the capillary microcirculation (by an increased expression of endothelial nitric oxide synthase), an effect that may contribute to the utilization of glucose by increasing the delivery of nutrients to tissues. Defects in these intracellular signaling pathways are an important cause of impaired insulin action, or "insulin resistance" (see Pathobiology of type 2 diabetes).

TABLE 210-2 THE METABOLIC EFFECTS OF INSULIN

METABOLIC EFFECT	STIMULATED BY INSULIN	INHIBITED BY INSULIN
Carbohydrate metabolism	Glucose uptake Glycolysis Glycogen synthesis	Glycogen breakdown Gluconeogenesis
Protein metabolism	Amino acid uptake Protein synthesis	Protein breakdown
Lipid metabolism	Triglyceride uptake Lipogenesis	Lipolysis Fatty acid oxidation

The overall actions of insulin tend to promote the uptake and storage of nutrients in the fed state and the release of nutrients from body stores in the fasting state (Table 210-2). The actions of insulin are dependent on its circulating concentration. In the fasting state, declining glucose concentrations inhibit the release of insulin, thereby increasing glycogenolysis and gluconeogenesis, as well as allowing the release of glucose into the circulation. In states of absolute or relative insulin deficiency, inadequate basal insulin concentrations allow unrestrained hepatic glucose production, which results in fasting hyperglycemia. In the absence of insulin resistance, however, any carbohydrate that is ingested (e.g., in the postprandial period) stimulates insulin secretion. At the very lowest concentrations, insulin inhibits lipolysis and the production of ketones. As its concentrations rise, insulin lowers hepatic glucose production by inhibiting the release of glucagon. This rise in the insulin-to-glucagon ratio prevents glycogenolysis and the breakdown of skeletal muscle protein, so glucose levels stop rising. Further insulin then increases the peripheral uptake of glucose into skeletal muscle and adipose tissue, thereby promoting the synthesis of protein and triglycerides and lowering plasma concentrations of glucose. Eventually, higher insulin concentrations stimulate the synthesis of glycogen and the uptake of amino acids in the liver and muscle.

Inadequate insulin concentrations in the fed state—either due to β-cell failure or to an impairment of insulin secretion or action—impedes peripheral (predominantly skeletal muscle) uptake of glucose, thereby contributing to postprandial hyperglycemia. Impaired suppression of hepatic glucose production also contributes to postprandial hyperglycemia in patients with diabetes.

DIAGNOSIS

Diabetes is diagnosed using one of several criteria, including the fasting plasma glucose concentration, the plasma glucose concentration after a standard 75-g oral glucose challenge (also known as the oral glucose tolerance test), and the percentage or concentration of glycated hemoglobin (HbA_{1c}) (Table 210-3). The diagnosis of diabetes can be confirmed by the presence of two abnormal tests (fasting, 2-hour oral glucose tolerance test or HbA_{1c}) or by finding both unequivocal hyperglycemia (random plasma glucose concentration >200 mg/dL [>11.1 mmol/L]) plus typical symptoms of polyuria, polydipsia, and weight loss. In the presence of a single abnormal test, a confirmatory test is needed on a different blood sample. In individuals in whom HbA_{1c} and glucose values are discordant, fasting and 2-hour plasma glucose levels are more accurate.

Because plasma glucose concentrations range on a continuum, the selection of a specific diagnostic threshold is in some respects arbitrary. Current criteria are based on the plasma glucose or HbA_{1c} concentration above which the risk of diabetes-specific microvascular complications (e.g., retinopathy) is perceptibly increased. In situations of altered red blood cell turnover or certain hemoglobinopathies, caution should be exercised, because HbA_{1c} may not accurately reflect the mean plasma glucose concentration (see later section on glycated hemoglobin). In those circumstances, direct glucose measurement should be used. HbA_{1c} values may vary with race and ethnicity independently of glycemia, with higher HbA_{1c} in Blacks and non-Hispanic Whites. Despite these racial differences, diagnostic values are the same because the risk of complications appears to be the same across ethnicities. Separate glucose criteria exist for the diagnosis of gestational diabetes (see Gestational Diabetes).

TABLE 210-3 DIAGNOSTIC CRITERIA FOR DIABETES

	NORMAL	IMPAIRED (PREDIABETES)	DIABETES
Fasting glucose concentration mg/dL (mmol/L)	<100 (5.6)	100-125 (5.6-6.9)	≥126 (7.0)
OGTT 2-hour glucose concentration mg/dL (mmol/L)	<140 (7.8)	140-199 (7.8-11.0)	≥200 (11.1)
HbA_{1c} (%)	<5.7	5.7-6.4	≥6.5
HbA_{1c} (mmol/mol)	<39	39-47	≥48

HbA_{1c} = glycated hemoglobin; OGTT = oral glucose tolerance test.
Data from American Diabetes Association Standards of Medical Care in Diabetes—2022. *Diabetes Care.* 2022;45(Suppl 1):S17-S38.

Impaired glucose regulation that does not meet the criteria for diabetes, termed "prediabetes" or "nondiabetic hyperglycemia," is defined by a fasting glucose concentration of 100 to 125 mg/dL [5.6 to 6.9 mmol/L], a 2-hour glucose concentration of 140 to 199 mg/dL [7.8 to 11.0 mmol/L], or an HbA_{1c} concentration of 5.7 to 6.4% [39 to 47 mmol/mol]. Each of these three approaches is equally appropriate to diagnose prediabetes. Individuals with prediabetes are at increased risk (a 25 to 50% higher relative risk in the next 5 years compared with individuals with normal glucose and HbA_{1c} values) for progressing to diabetes, but some will spontaneously revert to normal glucose regulation without any specific intervention, particularly individuals who are closest to the normal range.[2] Prediabetes is also associated with an increased risk of atherosclerotic cardiovascular disease, at least partially independent of the future development of diabetes.

HbA_{1c} results may be influenced by conditions that alter red cell survival. For example, the HbA_{1c} level is lower in patients with hemolytic anemia, hemoglobinopathies, renal impairment, and after splenectomy. Assay interference may also lead to misleadingly high HbA_{1c} levels with chronic use of opioids, salicylates, or alcohol. In situations in which capillary or interstitial glucose concentrations are incongruous with HbA_{1c} values, measurement of fructosamine (glycated serum protein) or glycated albumin, both of which reflect mean glucose concentrations during the preceding 2 to 3 weeks, may provide a more accurate assessment. However, these assays have not been as well standardized, and their relationship with mean plasma glucose is less well established.

TYPE 1 DIABETES

EPIDEMIOLOGY

New cases of type 1 diabetes may occur at any time of life, but the incidence peaks around the time of puberty. No sex differences are noted during childhood, but males are affected more commonly in early adult life. Early-onset diabetes carries a higher familial risk, and affected fathers are more likely to have offspring with type 1 diabetes (6 to 9%) than are affected mothers (1 to 3%).

The incidence varies greatly across the world, with rates as high as 60 per 100,000 per year in Scandinavia, up to 20 per 100,000 per year in Southern Europe and the United States, and as low as 3 per 100,000 per year in China.[3] In the United States approximately 30% of people with diabetes are diagnosed after young adulthood.[4] The worldwide annual incidence appears to have increased by 3 to 4% per year over the past 50 to 60 years, with the highest rates of increase in lower-incidence countries and the lowest rates of increase in countries with the highest incidence. This increasing incidence of type 1 diabetes also suggests that environmental factors may be pathogenic, but such factors remain largely undetermined.

PATHOBIOLOGY

In type 1 diabetes, a complex interplay of genetic, environmental, and autoimmune factors selectively targets insulin-producing pancreatic islet β cells and ultimately destroys them.[5] Type 1 diabetes is characterized by an absolute deficiency of insulin, and over 90% of newly diagnosed individuals have one or more autoantibodies to glutamic acid decarboxylase (GAD65), pancreatic islet β cells (tyrosine phosphatase IA-2), the IA-2b zinc transporter (ZnT8), or insulin. In normoglycemic relatives of people with diabetes, the presence of two or more antibodies is highly predictive of developing type 1 diabetes within 5 years. However, some people with type 1 have no evidence of autoimmunity and have what is termed idiopathic type 1 diabetes.

β-cell destruction is largely mediated by a variety of T-cell–mediated immune responses that cause apoptosis or cellular destruction, although evidence suggests that islet-directed antibodies may also play a role. Islet-targeted inflammatory cell infiltrates (termed insulitis), which are composed of $CD8^+$ and $CD4^+$ T cells, macrophages, and pancreatic β-cells, are linked to the onset of diabetes. Over time, the islets become completely devoid of β cells and inflammatory infiltrates. Other pancreatic cells remain intact, thereby illustrating the specificity of the autoimmune attack on β cells.

The role of genetic factors in type 1 diabetes is exemplified by familial clustering with other autoimmune endocrine disorders and a 30 to 40% concordance rate in identical twins, with a significant proportion of the remainder having autoantibodies. Nonidentical siblings who are human leukocyte antigen (HLA) identical to the proband have a 12 to 15% risk for development of diabetes by the age of 20 years. The presence of an environmental trigger for type 1 diabetes is highly likely, however, because even identical twins do not express identical T-cell receptor and immunoglobulin genes.

About 60 type 1 diabetes genes are known.[6] HLA genes are located on the short arm of chromosome 6 and contribute about 50% of genetic susceptibility. Two HLA class II haplotypes, DR4-DQ8 and DR3-DQ2, are present in about 90% of children with type 1 diabetes. The genotype containing both haplotypes carries the highest risk of diabetes (about 5%) and is most commonly seen in early-onset disease. In contrast, the DR15-DQ6 haplotype is highly protective, being found in only 1% of children with type 1 diabetes in contrast to 20% of the general population. Other genes that likely contribute to the genetic susceptibility to type 1 diabetes include the insulin gene (on chromosome 11) and several other loci that are associated with other autoimmune conditions, thereby suggesting the existence of common pathways that predispose to the loss of immune self-tolerance. Another gene, *IFIH1*, located on chromosome 2, encodes a protein involved in innate immunity and plays a role in recognition of the RNA genomes of certain viruses; high IFIH1 levels might provoke exaggerated antiviral immune responses that predispose to autoimmunity. Many other genes have also been implicated, thereby underscoring the polygenic nature of this disease.

Epidemics of mumps (Chapter 340), rubella (Chapter 339), and coxsackie virus (Chapter 349) infection have been associated with an increased frequency of type 1 diabetes, apparently because they may contain molecules that resemble a β-cell protein, nullify self-tolerance, and trigger an autoimmune response in genetically predisposed individuals. This process may also explain the increase in new-onset type 1 diabetes, often presenting as an acute hyperglycemic emergency, during the SARS-CoV-2 pandemic.[7]

A critical role for T cells is suggested by studies involving pancreatic transplantation in identical twins. When a monozygotic twin with diabetes receives kidney and pancreatic grafts from a genetically identical sibling who does not have diabetes, little or no therapeutic immunosuppression is required. However, these recipients eventually experience a resumption of insulitis, with the subsequent recurrence of diabetes. Evidence implicating T cells in diabetes autoimmunity also derives from clinical trials using immunosuppressive drugs. Drugs such as rituximab, cyclosporine, methotrexate, or antibodies directed against a component of the T-cell receptor (anti-CD3) or that alter antigen presentation by β cells (anti-CD20) slow the progression of recent-onset diabetes, but this effect is not sustained if immunosuppression is withdrawn.

In the less than 10% of individuals who require insulin from the time of diagnosis and who do not have autoantibodies, pancreatic β cells are destroyed by insults that primarily involve the exocrine pancreas but also damage the adjacent endocrine pancreas. This condition is occasionally known as type 3c diabetes. Typical examples include pancreatitis (Chapter 130), cystic fibrosis (Chapter 77), and hemochromatosis (Chapter 196). Drugs such as interferon gamma, diazoxide, pentamidine, and checkpoint inhibitors can also sufficiently damage β cells to cause insulin-dependent diabetes.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis of diabetes is usually made on clinical grounds based on symptoms or glucose criteria (see Table 210-2).[8] After what is commonly a long preclinical phase (Fig. 210-2), symptomatic hyperglycemia, manifested by polyuria, polydipsia, weight loss, and fatigue, occurs abruptly, usually in an otherwise healthy child or young adult.

At the time of clinical diagnosis, about 10 to 20% of the original β-cell mass may still be functional, and overt hyperglycemia with or without ketosis may

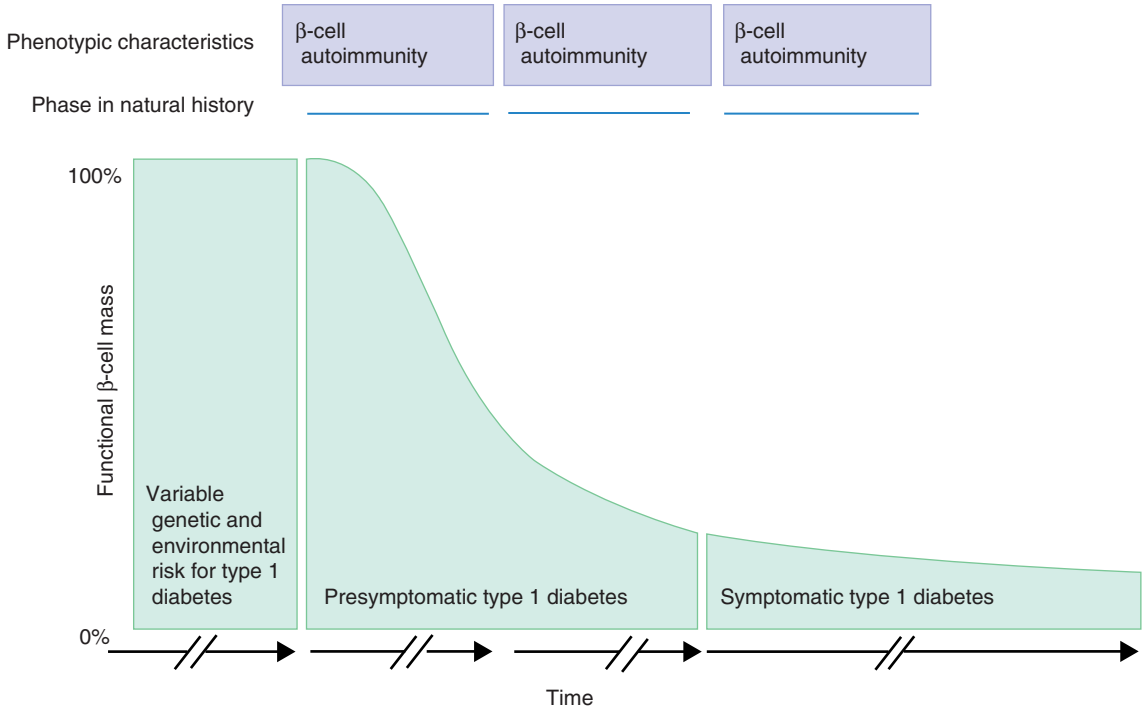

FIGURE 210-2. Summary of the sequence of events that lead to pancreatic β-cell loss and ultimately to the clinical evolution of type 1 diabetes. (From Insel RA, Dunne JL, Atkinson MA, et al. Staging presymptomatic type 1 diabetes: a scientific statement of JDRF, the Endocrine Society, and the American Diabetes Association. *Diabetes Care*. 2015;38:1964-1974.)

be precipitated when an unrelated medical illness or stress to an already-limited islet reserve triggers these clinical manifestations. The coincidence of type 1 diabetes with puberty is likely attributable to insulin resistance associated with increases in the secretion of sex and growth hormones.

In a minority of U.S. cases, but much more commonly in low- and middle-income countries, the initial presentation may be diabetic ketoacidosis if these milder symptoms were not recognized.[9] Worldwide, between 13% and 80% of individuals with type 1 diabetes present with diabetic ketoacidosis. Diabetic ketoacidosis at diagnosis is more common in children younger than age 5 years and in children whose families, often for social or economic reasons, do not have access to medical care.

The presence or absence of anti–glutamic acid decarboxylase (GAD65) or other antibodies (e.g., tyrosine phosphatase IA-2, the IA-2b zinc transporter, or insulin) is sometimes helpful to distinguish between type 1 and type 2 diabetes and to guide appropriate treatment if the diagnosis is in doubt. For example, when an individual presents in diabetic ketoacidosis but has features more typical of type 2 diabetes, such as obesity, a strong family history of type 2 diabetes, a prior history of gestational diabetes, or is over age 40 years, antibody levels may be the only way to confirm type 1 diabetes.

After initiation of insulin therapy and stabilization of plasma glucose concentrations, many patients may experience a period of weeks to months of relatively easily controlled hyperglycemia. This so-called "honeymoon phase" of type 1 diabetes results from amelioration of the underlying stress in an individual whose pancreatic function reflects severe, but not total, destruction of β cells with ongoing, albeit markedly reduced, insulin secretion. However, the underlying, ongoing, progressive autoimmune destruction continues, thereby leading to a decline in insulin production, which usually is undetectable after a few years, at which time they rather suddenly (i.e., over a few weeks or months) have a marked increase in their exogenous insulin requirements to maintain normal plasma glucose concentrations. With highly sensitive C-peptide assays, low levels of insulin production are detected in some people who have long-standing type 1 diabetes and who demonstrate more stable glycemic control and lower rates of hypoglycemia. In some individuals with type 1 diabetes in adulthood, the clinical presentation may follow a more indolent course (termed latent autoimmune diabetes in adults), perhaps because the β-cell mass declines at a slower pace. Indeed, for some of these individuals, their diabetes may be initially misdiagnosed as type 2 diabetes until the progression of insulin deficiency reveal-s the phenotype of permanent and complete insulin dependence.

TREATMENT

The key to successful treatment of type 1 diabetes is to maintain glucose concentrations within the physiologic target range using insulin replacement therapy to prevent the short- and long-term harmful consequences of hyperglycemia. All individuals with type 1 diabetes should be primarily managed by an endocrinologist or, in locales where primary endocrinology is not available, in close concert with a consulting endocrinologist. Automated or semi-automated insulin delivery systems, which require expert supervision, permit a much better approximation of normal physiology and an increase in the amount of time that glucose values are in the physiologic range.[10] However, successful achievement and maintenance of aggressive glucose management require significant commitment by the person with diabetes and by their multidisciplinary team of health care clinicians.

Insulin Therapy

Everyone with type 1 diabetes requires exogenous insulin treatment to maintain life. The approach to insulin replacement in type 1 diabetes (Table 210-4) requires consideration of basal insulin requirements (i.e., the amount of insulin required to maintain homeostasis in the fasting state) and prandial insulin (i.e., the amount required for the influx of carbohydrates that occurs with meals). Insulin can be classified into rapid-acting insulin analogues, regular (short-acting) insulin, intermediate-acting insulin, long-acting insulin analogues, premixed insulin, and premixed insulin analogues (Table 210-4). In comparison with human insulin, the rapid and long-acting insulin analogues have the advantage of producing less hypoglycemia and weight gain, but they are more expensive.

Insulins can be administered by prefixed syringes or in vials. Insulin pen devices can be disposable (i.e., discarded when the insulin is used up) or contain cartridges that can be changed. From a safety perspective, insulin should be prescribed by the full brand name, including the number in the brand name, if applicable. If prescribed by hand, the term "units" rather than "u" should be used to avoid misinterpretation.

Intermittent Subcutaneous Insulin

Subcutaneous insulin replacement regimens vary from one to five or more injections per day depending on the individual's lifestyle, whether they count carbohydrates, and their preferences. People with type 1 diabetes are often treated with a combination of long-acting "basal" insulin and short-acting mealtime "prandial" insulin, using a multiple daily insulin injection ("basal-bolus") regimen.

The total daily insulin requirement for adults with type 1 diabetes is between 0.3 and 1.0 unit/kg/day, with half of the total daily dose typically given as basal insulin and the remainder divided into premeal boluses. Prandial insulin doses are determined by the meal's carbohydrate content plus a "correction factor" if the glucose level is elevated before the meal. For example, a common approach is to use 1 unit for every 10 to 15 g of a meal's carbohydrate content plus a correction factor of 1 unit to lower the plasma glucose concentration by 20 to

TABLE 210-4 INSULIN PREPARATIONS

TYPE OF INSULIN	ONSET OF ACTION	PEAK EFFECT	DURATION OF ACTION
PRANDIAL INSULIN (RAPID-ACTING ANALOGUES)			
Lispro (U100 or U200), aspart, glulisine	15-30 minutes	30-90 minutes	3-4 hours
SHORT-ACTING INSULIN ("REGULAR")			
Human (U100 or U500)	Approximately 30 minutes	2-4 hours	5-8 hours
INTERMEDIATE-ACTING INSULIN ("NPH")			
Human	2-4 hours	6-10 hours	16-20 hours
LONG-ACTING INSULIN			
Glargine U100	1.5-2 hours	Peakless	16-20 hours
Detemir	1.5-2 hours	Peakless	16-20 hours
Degludec U100 or U200	1.5-2 hours	Peakless	36-40 hours
Glargine U300	1.5-2 hours	Peakless	30-36 hours

NPH = neutral protamine Hagedorn. Not all preparations are available everywhere.

50 mg/dL (about 1 to 3 mmol/L). However, insulin requirements are influenced by several factors that may or may not be under the control of the person living with diabetes (e.g., age, body size, insulin sensitivity, exercise, menstrual cycle, comorbid conditions, medication use) and often vary substantially among individuals, so these algorithms must be individualized. Critical to the success of physiologic insulin replacement is the need for the individual to monitor blood or interstitial glucose concentrations, generally several times a day. Monitoring, which typically relies on small portable meters with disposable strips before meals and at bedtime, allows for appropriate dosing, correction of unexpected hyperglycemia, and detection or confirmation of hypoglycemia. Several mobile phone applications and computer programs are available to assist with this calculation.

In addition to glucose testing, people who are taking insulin should be instructed to test their urine or capillary ketones (with a reagent strip) in situations in which the blood glucose concentration is unexpectedly and persistently elevated. Moderate or large amounts (≥2+ ketone readings or >1.5 mmol/L) may indicate the onset of diabetic ketoacidosis (see later) and should prompt the individual to seek urgent medical attention.

Continuous Insulin Infusion

Many people with type 1 diabetes are now administered insulin using a continuous subcutaneous infusion system, commonly termed an insulin pump. These systems consist of a control unit and an insulin reservoir, which can be attached by thin flexible tubing to a very small catheter that is inserted subcutaneously by the patient and changed every 2 or 3 days. These frequent changes of the infusion site help to avoid local inflammation and fibrosis, which can interfere with insulin absorption. Insulin pumps are also available as tubeless systems, inserted into the abdomen, flank, upper leg, or arms. Compared with intermittent subcutaneous insulin, insulin pump therapy reduces HbA_{1c} concentrations by 0.3 to 0.6% (3 to 7 mmol/mL) and also reduces the risk of severe hypoglycemia.[A1] When used appropriately, these systems can maximize the control of blood glucose levels and allow a more flexible lifestyle.

Insulin pumps, which require expert supervision, can deliver a rapid-acting insulin analogue at a variable rate. Pumps can be programmed to deliver one or multiple basal infusion rates as well as preprandial bolus doses. The basal insulin delivery rate, which is often programmed to vary throughout the day, may be especially useful to prevent hyperglycemia associated with the "dawn phenomenon" (a rising blood glucose concentration in the few hours before waking, thought largely to be due to increased secretion of counter-regulatory hormones). In addition, on-demand changes to basal rates (temporary basal rates) can increase or decrease insulin delivery when requirements change, such as at the time of physical activity. Periprandial bolus doses and correction doses are calculated by the pump based on preprogrammed settings for insulin to carbohydrate ratios, insulin sensitivity factors, the premeal glucose level, and even the carbohydrate content of the meal. The person with diabetes or their caregiver must be well-versed regarding how to use the pump and how to revert quickly to multiple daily subcutaneous insulin injections in the event of a pump malfunction, because metabolic decompensation, including diabetic ketoacidosis, can develop within a few hours since the half-life of insulin is just 5 to 10 minutes and since patients do not have a reservoir of long-acting insulin.

Insulin pump systems can include continuous glucose monitoring devices that measure glucose levels in the interstitial fluid and provide data regarding glucose trends after meals, during physical activity, and at night. Pump features can include automated glucose-responsive adjustments to the insulin dose, including suspending the delivery of insulin when a low glucose level is predicted to occur. Many systems can be programmed to sound an alarm when the glucose concentration goes outside of a preset range or rate of change. These sensor augmented pumps result in improvements in HbA_{1c} of −0.4 to −0.6% (4 to 7 mmol/mol) compared with traditional multidose insulin injections in patients with type 1 diabetes and also reduce the risk of hypoglycemia.[A2,A3]

Closed-loop insulin delivery systems or automated insulin delivery (consisting of real-time glucose monitoring and an integrated insulin control algorithm) automatically change the delivery rate of insulin by increasing, decreasing, or suspending the insulin infusion every 5 to 10 minutes to a preset glucose concentration, with the added feature of an automatic corrective bolus of insulin to mitigate hyperglycemia when a specific predetermined glucose value is reached. These "artificial pancreas systems" can improve glucose control and reduce hypoglycemia compared with conventional insulin pumps.[A4–A6] In addition to commercially available products, open-source software has been used to help people with diabetes to develop their own widely shared, closed-loop systems.

Inhaled insulin is also available but rarely recommended, except in a few specialized centers. Oral insulins, topical gels, and microneedles are in development but not ready for routine clinical use.

Adjunctive Therapies

Pramlintide (15 μg as a starting dose and increased every few days to the maintenance dose of 120 μg) is a subcutaneous injectable amylin analogue that can mitigate postprandial hyperglycemia, modestly lower the HbA_{1c} level (0.3 to 0.5% [3 to 6 mmol/mol]), and facilitate weight loss. However, it is rarely used because of associated nausea and the need for additional injections.

Low-dose dapagliflozin, which is a sodium glucose cotransporter 2 (SGLT2) inhibitor, and sotagliflozin, which is a SGLT1/2 inhibitor, cause glycosuria, reduce HbA_{1c} levels by 0.28 to 0.48% [3 to 6 mmol/mol], and facilitate weight loss. However, these agents can precipitate diabetic ketoacidosis in 3 to 6% of individuals with type 1 diabetes and also increase the risk of developing urinary and genital yeast infections. Based on these pros and cons,[11] these agents are approved for type 1 diabetes in many parts of the world but not in the United States or United Kingdom.

Diet and Lifestyle Treatment

In type 1 diabetes, the goal of dietary planning is an accurate estimation of the carbohydrate content of a meal to allow appropriate prandial insulin dosing. This goal can be approached by encouraging meal-to-meal carbohydrate consistency, which allows for a relatively fixed premeal insulin dose. A more flexible approach, however, is for individuals to learn "carbohydrate counting," which specifies an insulin dose per amount of carbohydrate in the meal. The ratio of insulin to carbohydrate can vary according to time of day. This approach requires substantial education, including how to read and understand nutritional information on food packaging, experience, and health literacy.

Dietary management should be individualized based on food preferences, religious or cultural needs, finances, schedules, physical activity, and glycemic targets. In general, rapidly absorbed carbohydrate foods ideally should be avoided, but caloric restriction is neither required nor helpful except in overweight or obese individuals. A "heart healthy" Mediterranean diet (see Fig. 13-1) is recommended as for the general population.

Whole Pancreas and Islet Cell Transplantation

Whole pancreas transplantation can achieve 5-year graft survival rates of about 70%, but the surgery is complicated, and lifelong immunosuppression is required. Pancreatic transplantation is generally reserved for persons who already have had or are concurrently receiving a kidney transplant. Otherwise, a pancreas-only transplant may be considered for individuals who have a history of frequent, acute, and severe metabolic complications (especially severe hypoglycemia) or severe and incapacitating psychosocial problems related to insulin therapy.[12]

Pancreatic islet cell transplantation is generally an experimental procedure, also requires systemic immunosuppression, and is performed in only a few centers, usually in the setting of a research study. Stem cell therapy is an active area of investigation.

PREVENTION

Proposed preventive options include primary prevention, aimed at inhibiting the development of autoimmunity against islet autoantigens; secondary prevention, aimed at halting the autoimmune processes and possibly avoiding the clinical onset of diabetes in individuals with multiple islet autoantibodies; and tertiary prevention, to slow the β-cell destructive process and to avoid or delay the onset of diabetes-related complications in individuals with newly diagnosed diabetes. A single 14-day course of the monoclonal antibody teplizumab may delay progression to clinical type 1 diabetes in high-risk relatives of people with type 1 diabetes,[A7] but no preventive intervention has shown more than limited short-term success.

PROGNOSIS

Substantial progress has been achieved in reducing the microvascular complications of type 1 diabetes (see later), largely due to more intensive glucose control as well as more effective treatment of early stages of renal disease (Chapter 109) and retinopathy (Chapter 391). Morbidity and mortality from macrovascular complications also have declined, largely due to adjunctive treatments such as lipid lowering using statins (Chapter 190) and aggressive blood pressure control using inhibitors of the renin-angiotensin-aldosterone pathway (Chapter 64).

For example, less than 1% of individuals with diabetes now become blind, require renal replacement, or have amputation due to diabetes. In the absence of renal disease, life expectancy for people with type 1 diabetes in the United States is comparable to that of the general population, but the overall mortality rate of individuals with type 1 diabetes from age 35 years onward is about twice as high as in the general population because of the presence of microvascular and macrovascular disease. As a result, affected individuals with diabetes remain at significantly higher risk (five- to six-fold higher) of all-cause and cardiovascular mortality compared with individuals who do not have diabetes.[13] Glycated hemoglobin concentrations 7.5% (58 mmol/mol) or higher or less than 5.6% (38 mmol/mol) in persons with diabetes are associated with an increased risk of all-cause mortality,[14] and the risk becomes progressively higher for HbA_{1c} concentrations above 7.9% (63 mmol/mol). Unfortunately, large variations in risk are associated with health care disparities, including by race, ethnicity, and socioeconomic status.

TABLE 210-5 RISK FACTORS FOR TYPE 2 DIABETES

Age ≥45 years
First-degree relative with diabetes
Personal history of cardiovascular disease
Overweight or obese
Sedentary lifestyle
Member of an at-risk racial or ethnic group: Asian, African American, Hispanic, Native American, or Pacific Islander
HDL-C <35 mg/dL (0.90 mmol/L) and/or a triglyceride level >250 mg/dL (2.82 mmol/L)
Impaired glucose tolerance, impaired fasting glucose
Polycystic ovarian syndrome
Acanthosis nigricans
Nonalcoholic fatty liver disease
Hypertension or on therapy for hypertension
History of gestational diabetes or delivery of a baby weighing more than 4 kg (9 lb)
Antipsychotic therapy for schizophrenia and/or severe bipolar disease
Sleep disorders, including obstructive sleep apnea, chronic sleep deprivation, and night-shift occupation
Long-term use of glucocorticoid therapy

HDL-C = high-density lipoprotein cholesterol.
Testing should be considered in all adults who are obese (BMI ≥30 kg/m^2) as well as in adults who are overweight (BMI 25 to <30 kg/m^2 or >23 kg/m^2 in Asians/Asian Americans) and also have any additional risk factors.

TYPE 2 DIABETES

EPIDEMIOLOGY

Type 2 diabetes affects more than 34 million people in the United States, where its prevalence increased from approximately 0.93% of the population in 1958, to 3% in 1995, 9% in 2015, and 10.5% in 2020.[15] Among adults, type 2 diabetes affects 13% of adults older than age 18 years and 27% of adults age 65 years or older. This increase is in part due to the aging of the population, but incidence rates are also increasing parallel to the rise of overweight and obesity (Chapter 201) as well as increasingly sedentary lifestyles. The rates of diabetes are highest among Native Americans/Alaska Natives, Hispanic Americans, and non-Hispanic Blacks, followed by non-Hispanic Asians and non-Hispanic Whites (7.5%). The prevalence of type 2 diabetes also varies significantly by education level, affecting 13.3% of adults with less than a high school education compared with 9.7% of adults with a high school education and 7.5% of adults with more than a high school education.

A similar pattern is observed globally. In 2021, an estimated 537 million people worldwide (10.5% of all adults age 20 to 79 years) had diabetes,[16] including an estimated 24% of adults over age 75 years. By 2045, about 783 million adults worldwide are projected to have diabetes. The prevalence of diabetes is higher in urban than in rural areas, but men and women have about an equal prevalence. Countries with the largest numbers of adults with diabetes are China (140 million), India (74 million), and Pakistan (33 million).

PATHOBIOLOGY

The development of type 2 diabetes is the result of interaction between environmental factors and a strong hereditary component (Table 210-5). Type 2 diabetes is caused by a combination of two primary metabolic factors: defective secretion of insulin by pancreatic β cells and the inability of insulin-sensitive tissues to respond appropriately to insulin. The relative contribution of these factors varies among individuals and even within the same individual over time because the secretion of insulin progressively declines with a longer duration of disease.

Impaired Insulin Secretion

The failure of β cells to provide enough insulin is a combination of insufficient β-cell mass and altered β-cell function. By the time of diagnosis of type 2 diabetes, up to 50% of β cells may have failed, but a 50% surgical pancreatectomy does not lead to hyperglycemia in otherwise healthy individuals. Physiologic studies show β-cell dysfunction in the early stages of type 2 diabetes, with diminished pulsatile and oscillatory release of insulin and downregulation of the pancreatic insulin receptor. An increased accumulation of amyloid in the islet cells may contribute to impaired secretory function.

Impaired Insulin Action (Insulin Resistance)

Most individuals with type 2 diabetes are overweight or obese, conditions that are associated with insulin resistance (a state of reduced insulin-mediated uptake of glucose). Resistance to insulin's action, primarily in muscle and fat but also in the liver, is typically the first abnormality. Insulin resistance stimulates compensatory hyperinsulinemia in an attempt to maintain normal glucose concentrations. Over time, hyperglycemia occurs as the consequence of the inability of β cells to produce enough insulin; subsequent pancreatic exhaustion results in insulinopenia.

Genetics

The lifetime risk of developing type 2 diabetes is 40% for individuals who have one parent with type 2 diabetes and 70% if both parents are affected. First-degree relatives of individuals with type 2 diabetes are about three times more likely to develop the disease than are individuals without a positive family history of the disease. The concordance rate among monozygotic twins is as high as 70%, whereas the concordance rate in dizygotic twins is only 20 to 30%.

Single-Gene Mutations

Monogenic defects include maturity-onset diabetes of the young (MODY), which is an autosomal dominant disorder in which mutations of at least 11 different genes can impair insulin secretion. Maturity-onset diabetes of the young accounts for 1 to 3% of diabetes diagnosed under age 30 years (about 0.4% of all diabetes). Maturity-onset diabetes of the young type 2 is associated with a mutation of glucokinase, which acts as a glucose sensor within the β cell. Higher levels of glucose are required to stimulate the release of insulin from the β cell. Maturity-onset diabetes of the young type 3 is due to a mutation of the gene for hepatic nuclear factor 1α, which is involved in early pancreatic development and in the regulation of insulin gene expression. Other forms of maturity-onset diabetes of the young have been described in only a few families.

Polygenic Risk

Common forms of type 2 diabetes are likely polygenic and represent a complex interaction between genes and the environment. More than 100 genetic risk loci collectively explain less than 15% of the heritability of the disorder. Other than rare variants that are unique to specific ethnic groups, the gene with the strongest effect size to date (odds ratio for diabetes, 1.4) is *TCF7L2*, which, like most other recognized gene variants, is associated with reduced insulin secretion. Other risk loci include a β-cell zinc transporter (ZnT-8; odds ratio, 1.15), the sulfonylurea receptor (*KCNJ11*; odds ratio, 1.1), and melatonin receptor 1B (*MTNR1B*; odds ratio, 1.1). A smaller number of gene variants associated with insulin resistance include genes encoding peroxisome proliferator-activated receptor γ (odds ratio, 1.2) and insulin receptor substrate 1 (odds ratio, 1.1). Sequence variants in *SLC16A11*, a gene that is involved in intracellular lipid metabolism, is a relatively common risk allele (odds ratio, 1.29) in Mexican populations.

Epigenetic Risk

Epigenetic changes may play an important role in the development of type 2 diabetes via DNA methylation, histone acetylation, and noncoding RNAs

that regulate gene expression in response to environmental cues. Epigenetic changes can persist for an individual's lifetime and can be passed on over two to three generations. Epidemiologic studies suggest that both fetal starvation and fetal overnutrition predispose to type 2 diabetes in adult life. Some or most of this risk is thought to be due to epigenetic changes in yet-unspecified genes.

Obesity

Nearly 90% of individuals with type 2 diabetes are overweight or obese (Chapter 201), and overweight or obesity is the single most important clinical predictor of type 2 diabetes, particularly for young or middle-aged individuals. For example, women with a body mass index (BMI) 35 kg/m^2 or greater have over a 90-fold higher odds of developing diabetes than do women with a BMI of less than 22 kg/m^2. The relationship between BMI and type 2 diabetes is linear, and an increased risk can be observed even within the BMI range defined as normal (18.5 to 25 kg/m^2).

The distribution of body fat also plays an important role, with abdominal obesity being more predictive. Compared with fat at other sites, abdominal obesity is associated with a higher secretion of proinflammatory cytokines, lower secretion of adiponectin (which is an anti-inflammatory adipokine), and the production of free fatty acids, which contribute to insulin resistance and β-cell failure. Ectopic accumulation of adipose tissue in the liver, often manifested as nonalcoholic fatty liver disease (Chapter 138), is also strongly associated with an increased risk of diabetes. Increased lipid accumulation in pancreatic islets may impair the secretion of insulin.

Other Risk Factors

Sleep deprivation (Chapter 374) is associated with important adverse cardiometabolic outcomes, including weight gain, obesity, diabetes, cardiovascular disease, hypertension, and stress. Cigarette smoking increases the risk of developing type 2 diabetes. For example, men who smoke 25 or more cigarettes per day have a 1.94 increased relative risk of incident diabetes compared with nonsmokers, and risk of developing diabetes increases with the number of cigarettes smoked per day.

CLINICAL MANIFESTATIONS

The clinical presentation of type 2 diabetes is quite variable. Classic symptoms of polyuria, polydipsia, and weight loss occur only in the presence of substantive hyperglycemia, so most patients with mild hyperglycemia (<180 mg/dL [10.0 mmol/L]) may remain asymptomatic for many years.

When the plasma glucose level exceeds the renal threshold for glucose reabsorption (about 180 to 200 mg/dL [10.0 to 11.1 mmol/L]), glycosuria leads to an osmotic diuresis, which is manifested by polyuria. Persistent glycosuria leads to hypovolemia that causes polydipsia, but increased thirst and polyuria may not be noticed because they develop slowly in most individuals. Significant glycosuria can lead to weight loss. Nonspecific symptoms such as fatigue are common.

Due to the insidious onset and delayed recognition, many individuals present with long-term microvascular complications (see later), including retinopathy (Chapter 391), neuropathy (Chapters 384 and 388), and nephropathy (Chapter 109). Among U.S. adults with type 2 diabetes, the prevalence of retinopathy or blindness is almost 12%, the prevalence of chronic kidney disease, defined as albuminuria or reduced renal function, is more than 40%, and the prevalence of diabetic neuropathy is as high as 50%.

Macrovascular complications, including ischemic cardiovascular disease (Chapter 40), heart failure (Chapter 45), peripheral vascular disease (Chapter 65), and cerebrovascular disease (Chapter 376), are the leading causes of morbidity and mortality in people with type 2 diabetes, who have approximately a 2- to 2.5-fold higher risk of developing cardiovascular disease and heart failure. Every 18 mg/dL (1.0 mmol/L) increase in the fasting glucose levels increases the estimated risk of cardiovascular events or death by 17%. Common medical conditions coexisting with type 2 diabetes (e.g., obesity [Chapter 201], hypertension [Chapter 64], and dyslipidemia [Chapter 190]) are important risk factors for cardiovascular disease, but diabetes itself confers independent risk.

DIAGNOSIS

Since most people with type 2 diabetes are asymptomatic for many years, screening of asymptomatic individuals is recommended by age 35 years in persons who have multiple risk factors (Table 210-5) to minimize the development of subsequent microvascular and macrovascular complications. The diagnosis is based on the fasting blood glucose level or the hemoglobin A_{1c} level, occasionally supplemented by an oral glucose tolerance test (see Table 210-2).

TREATMENT

Effective treatment of type 2 diabetes encompasses management of lifestyle interventions (including diet, exercise, and weight control), use of multiple oral or injectable medications, self-management and self-monitoring of blood glucose concentrations, and surveillance and treatment for acute and chronic diabetic complications.

The primary goals of treating type 2 diabetes are to prevent symptomatic hyperglycemia and to prevent the microvascular and macrovascular complications of diabetes by lowering glucose concentrations. The glucose targets should be individualized, based on the patient's life expectancy, prior vascular complications, cardiovascular risk factors, comorbid conditions, risk for hypoglycemia, and cognitive and psychological status. HbA_{1c}, which is considered the gold standard for monitoring chronic glycemia, reflects an average of blood glucose levels over the past 3 months and is associated with the long-term risk for developing long-term diabetes-related complications. In general, lowering the HbA_{1c} level to 7% (53 mmol/mol) or below is an appropriate goal for most individuals, but more stringent glycemic control (HbA_{1c} <6.5% [48 mmol/mol]) may be appropriate for some young people with a short duration of disease if it can be achieved without precipitating excessive hypoglycemia. Less stringent glycemic goals (HbA_{1c} 7 to 8% [53 to 64 mmol/mol]) are appropriate for individuals with a history of severe hypoglycemia, hypoglycemia unawareness, limited life expectancy, advanced renal disease, or extensive comorbid conditions. The HbA_{1c} level should be measured at least semiannually in anyone with diabetes and at least quarterly in those who are not meeting their glycemic target. Generally accepted targets for fasting and postprandial glucose levels are 80 to 130 mg/dL (4.4 to 7.2 mmol/L) and less than 180 mg/dL (10.0 mmol/L), respectively. In persons not on insulin, HbA_{1c} monitoring is generally preferred over home blood glucose monitoring.

Although HbA_{1c} is the cornerstone of monitoring most patients with type 2 diabetes, the HbA_{1c} level does not inform patients about blood glucose values on a daily basis, so measurements of blood glucose levels are often necessary for the day-to-day management, especially in patients who require insulin therapy. Blood glucose levels can be self-monitored using capillary (finger stick) testing, but continuous glucose monitoring, which measures interstitial glucose every 5 to 15 minutes, provides a comprehensive 24-hour glycemic assessment, detects nocturnal hyperglycemia, and may be an option when type 2 diabetes requires insulin therapy. However, this technology is not available for most people with type 2 diabetes, mainly due to cost.

Self-Management Education and Support

The active participation of the affected individual, which is critical for successful management of type 2 diabetes and can improve glycemic control by as much as a 1% (11 mmol/mol) reduction in the HbA_{1c} concentration, reduces the onset and/or progression of diabetic complications and improves quality of life.[17] Initial education and support are typically provided by an expert health professional who addresses the individual's health beliefs, cultural needs, current knowledge, physical limitations, emotional concerns, family support, financial status, health literacy, and other factors that influence the ability to meet the challenges of self-management. The seven major behaviors related to diabetes self-care management include diet, physical activity, monitoring blood glucose concentrations, adherence to proper medication, good problem solving, coping skills, and risk reduction behavior.

Lifestyle intervention provides ongoing counseling, coaching, or individualized guidance to help people with type 2 diabetes to change their diet (Chapter 13), level of physical activity (Chapter 14), or both.[A8] Dietary guidance, preferably by a registered dietician with quarterly follow-up, improves glycemic control, reduces reliance on medication, and helps reduce cardiovascular risk factors by achieving and maintaining modest (approximately 5 to 10% of body weight) weight loss, moderating carbohydrate intake, and avoiding concentrated sweets and foods high in saturated fats and cholesterol (Chapters 13 and 190). A Mediterranean diet (Fig. 13-1), the Dietary Approaches to Stop Hypertension (DASH) diets (Table 13-4), or a vegetarian or vegan diet are safe and effective ways to lose weight, but the Mediterranean diet is best studied for reducing cardiovascular disease events and mortality. However, very low carbohydrate diets must be avoided in patients who are treated with SGLT2 inhibitors or insulin because of the risk of developing diabetic ketoacidosis.

Physical activity (Chapter 14) improves glycemic control and reduces the risk of developing cardiovascular disease in people with type 2 diabetes. The American Diabetes Association recommends at least 150 minutes per week of moderate (50 to 70% of an individual's maximum heart rate) to vigorous (>70% of an individual's maximum heart rate) physical activity for people with type 2 diabetes. For example, walking 1 hour per day improves physical fitness, body composition, and glycemic control in people with type 2 diabetes. Brisk walking for at least 30 min/day (e.g., ≥15 MET-hours per week) improves insulin sensitivity, glycemic control, and the incidence of obesity. Screening stress testing is not recommended in asymptomatic individuals, but some diabetes-related complications may restrict certain activities. For example, vigorous aerobic or resistance exercise can precipitate retinal hemorrhage or detachment in people who have proliferative retinopathy (Chapter 391). Significant sensory loss due to peripheral neuropathy (Chapter 388) can increase the risk of foot injury or falling. People who have poorly controlled diabetes may develop hyperglycemia during

TABLE 210-6 NONINSULIN MEDICATIONS FOR TYPE 2 DIABETES

DRUG	DRUG FORMULATIONS	DOSING	ADVERSE EFFECTS
1. Biguanides (oral): decrease glucose release from liver; decrease intestinal absorption of glucose; improve insulin sensitivity (increase glucose uptake and utilization)			
a. Metformin	500 mg, 850 mg, 1000 mg tablets	Initial: 500 mg twice daily or 850 mg once daily Range: 500-2550 mg	Gastrointestinal symptoms (diarrhea, nausea, upset stomach), metallic taste, lactic acidosis (0.03 cases/1000 people)
	XR: 500 mg, 750 mg tablets	Initial: 500 mg once daily Range: 500-2000 mg once daily	
2. Sodium-glucose cotransporter-2 inhibitors (oral): increase glucose excretion in the urine			
a. Canagliflozin	100 mg, 300 mg tablets	Initial: 100 mg once daily Range: 100-300 mg daily	Urination or urgency, lower blood pressure, dizziness, genital yeast infections, urinary tract infections, increase in blood potassium; rare severe allergic reactions (swelling of tongue, throat, face or body; severe rash); very rare – diabetic ketoacidosis
b. Dapagliflozin	5 mg, 10 mg	Initial: 5 mg once daily Range: up to 10 mg	
c. Empagliflozin	10 mg, 25 mg tablets	Initial: 10 mg once daily Range: up to 25 mg	
3. Glucagon-like peptide-1 agonists: increase insulin secretion, reduce glucose release from liver after meals, delay food emptying from stomach, and promote satiety. Do not use in patients with medullary thyroid cancer.			
a. Liraglutide	3 mL pen that delivers doses of 0.6 mg, 1.2 mg, or 1.8 mg once daily, inject subcutaneously; available as a pen device.	Initial: 0.6 mg SQ Range: up to 1.8 mg SQ	Nausea, headache, hypoglycemia (when used with insulin secretagogue), may cause weight loss, rare reports sudden pancreatitis
b. Exenatide	5 μg or 10 μg by subcutaneous pen device 2 mg sustained release given subcutaneously weekly	Initial: 5 μg twice daily Range: up to 10 μg SQ SQ weekly	
c. Lixisenatide	10 μg or 20 μg by subcutaneous pen device	Initial: 10 μg SQ daily Range: up to 20 μg SQ	
d. Dulaglutide	0.5 mL pen that delivers doses of 0.75 mg, 1.5 mg, 3 mg, or 4.5 mg once weekly; inject subcutaneously	Initial: 1.5 mg weekly SQ (0.75 mg in vulnerable populations) Range: up to 4.5 mg SQ weekly	
e. Semaglutide (SQ injection)	1.5 mL pen that delivers 0.25 mg, 0.5 mg, or 1 mg once weekly, inject subcutaneously	Initial: 0.25 mg weekly SQ Range: up to 1 mg SQ weekly (for obesity this may be up to 2.4 mg weekly)	
f. Semaglutide (oral)	3 mg, 7 mg, or 14 mg tablets	Initial:3 mg orally daily (empty stomach, half a glass of water, then nothing to eat or drink for 30 minutes) Range: up to 14 mg daily	
g. Tirzepatide (GLP/GIP dual receptor agonist)	2.5 mg, 5 mg, 7.5 mg, 12.5 mg, and 15 mg once weekly, inject subcutaneously; available as a pen device	Initial: 2.5 mg SQ weekly Range: up to 15 mg SQ weekly	
4. Dipeptidyl peptidase 4 inhibitors (oral): increase insulin secretion, reduce glucose release from liver after meals			
a. Alogliptin	6.25 mg, 12.5 mg, 25 mg tablets	Initial dose: 25 mg once daily Range: 6.25–25 mg once daily	Stuffy or runny nose, sore throat, headache, upper respiratory infection, rare severe allergic reaction (swelling of tongue, throat, face, or body; severe rash), rare reports of pancreatitis, no weight gain
b. Sitagliptin	25 mg, 50 mg, 100 mg tablets	Initial dose: 100 mg once daily Range: 25-100 mg	
c. Saxagliptin	2.5 mg, 5 mg tablets	Initial dose: 2.5 or 5 mg once daily Range: 2.5-5 mg	
d. Vildagliptin	50 mg tablets	Initial dose: 50 mg once daily Range: up to 50 mg twice daily	
e. Linagliptin	5 mg tablets	5 mg once daily	
5. Selected single-pill combinations			
a. Sitagliptin/metformin	50 mg/500 mg, 50 mg/1000 mg	Initial: 50 mg/500 mg or 50 mg/1000 mg twice daily Range: up to 100 mg/2000 mg	Stuffy or runny nose, sore throat, headache, upper respiratory infection, rare severe allergic reaction (swelling of tongue, throat, face, or body; severe rash), rare reports of pancreatitis, no weight gain
b. Sitagliptin/metformin XR	50 mg/500 mg, 50 mg/1000 mg tablets	Initial: 100 mg/1000 mg daily Range: up to 100 mg/200 mg	
c. Saxagliptin/metformin XR	5 mg/500 mg, 5 mg/1000 mg, 2.5 mg/1000 mg	Initial: 5 mg/500 mg or 5 mg/1000 mg once daily Range: up to 5 mg/2000 mg	
6. Insulin secretagogues (oral): sulfonylureas			
a. Tolbutamide	500 mg tablets two to three times daily	Initial: 1000-2000 mg daily Range: 250-2000 mg	Hypoglycemia and weight gain
b. Glimepiride	1 mg, 2 mg, 4 mg tablets once daily	Initial: 1-2 mg Range: 1-8 mg	
c. Gliclazide	40 mg or 80 mg tablets up to twice a day	Initial: 40 mg once daily Range: up to 160 mg twice daily	
d. Glipizide	5 mg, 10 mg tablets once or twice daily	Initial: 5 mg Range: 2.5-40 mg[2]	
e. Glyburide/glibenclamide	1.25 mg, 2.5 mg, 5 mg tablets once or twice daily	Initial: 2.5-5 mg daily Range: 1.25-20 mg[2]	

TABLE 210-6 NONINSULIN MEDICATIONS FOR TYPE 2 DIABETES—cont'd

DRUG	DRUG FORMULATIONS	DOSING	ADVERSE EFFECTS
7. Insulin secretagogues (oral): glinides			
a. Repaglinide	0.5 mg tablets taken two, three, or four times daily	Initial: 1-2 mg daily (0.5 mg if A_{1c} <8%) Range: 0.5-16 mg Maximum dose per meal is 4 mg	Hypoglycemia
b. Nateglinide	60 mg or 120 mg three times daily	Initial: 120 mg three times daily (if A_{1c} close to goal, use 60 mg)	
8. Alpha-glucosidase inhibitors (oral): starch blockers—delay digestion and absorption of carbohydrates			
a. Acarbose	25 mg, 50 mg, 100 mg tablets three times daily	Initial: 25 mg three times daily Range: 75-300 mg (max 150 mg if <60 kg)	Flatulence
9. Thiazolidinediones (oral): decrease insulin resistance in the body (muscle and fat tissues)			
a. Pioglitazone (preferred over rosiglitazone)	15 mg, 30 mg, 45 mg	Initial: 15-30 mg daily Range: 15-45 mg, once daily	Anemia, edema from fluid retention, weight gain, macular edema, bone loss and fractures in women; may cause or worsen heart failure; cannot use if have liver problems or severe heart failure; requires liver monitoring. Possible risk of excess cardiovascular death with rosiglitazone
b. Rosiglitazone	2 mg, 4 mg, 8 mg once or twice daily	Initial: 4 mg daily Range: 4-8 mg	

SQ = subcutaneous; XL = extended release.

Adapted from Diabetes Education Online, Type 2 Non-Insulin Therapies: Table of Medications. Diabetes Teaching Center at the University of California, San Francisco. https://dtc.ucsf.edu/types-of-diabetes/type2/treatment-of-type-2-diabetes/medications-and-therapies/type-2-non-insulin-therapies/table-of-medications/. exercise due to the production of counter-regulatory hormones, such as growth hormone, epinephrine, or cortisol, whereas individuals who are treated with insulin and insulin secretagogues could develop hypoglycemia. Adjustment in the dosage of medications and monitoring of blood glucose levels during exercise is a prudent precautionary measure.

Moderate alcohol consumption is not prohibited, with the proper consideration of calorie intake (7 kcal/g) and hypoglycemic risk if alcohol is consumed without food, particularly in persons who are insulin-treated. However, excess alcohol intake can contribute to weight gain, hypertension, cardiomyopathy, and atrial fibrillation, as well as peripheral neuropathy, fatty liver, and dementia. Individuals should consume no more than 1 to 2 drinks per day (women, ≤1 drink per day; men, ≤2 drinks per day or 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of distilled spirits). Cigarette smoking (Chapter 363) substantially increases the risk of microvascular and macrovascular complications in patients with type 2 diabetes, and smoking cessation substantially reduces this risk.

Pharmacologic Therapy

Although weight control, physical activity, and nutrition form the foundation of effective management, most people with type 2 diabetes will require pharmacologic treatments, often multiple, to maintain recommended levels of glycemic control. Antidiabetic drugs can be categorized as agents that reduce excessive endogenous glucose production (gluconeogenesis) in the liver; stimulate the pancreas to secrete insulin; improve the sensitivity of peripheral tissues to insulin; enhance the effect of incretin; increase glycosuria; address other targets; or directly provide insulin or its analogues (Table 210-6). Monotherapy with most noninsulin antidiabetic agents can reduce HbA_{1c} concentrations by 0.5 to 2.0% (5 to 22 mmol/mol), so it is unlikely that any single agent will achieve the glycemic target in people who have an HbA_{1c} concentration greater than 8.5% (69 mmol/mol).[18]

Guidelines recommend a hierarchical, individualized approach to pharmacological therapy based on treatment goals; the patient's comorbid conditions; and the drug's potency, side effect profile, ease of administration, cost, and convenience (Fig. 210-3). General agreement suggests that metformin should be the initial therapy for most patients and that subsequent drugs (when needed) should be added to, but not replace, metformin, unless it is contraindicated or not tolerated. Lowering of glucose levels per se has not been shown to reduce future cardiovascular events in type 2 diabetes,[A9] but specific drugs have documented cardiovascular or renal benefits (e.g., SGLT2 inhibitors and sometimes glucagon-like peptide-1 receptor agonists) and therefore are preferred for patients with or at risk for these conditions, independent of their HbA_{1c} concentration.[19,20]

First-Line Drugs

Metformin

The biguanide drug metformin is the most widely used antidiabetic medication and is considered the preferred initial therapy for people with type 2 diabetes. Metformin lowers blood glucose by reducing the hepatic glucose gluconeogenesis, but it also may enhance insulin sensitivity and limit intestinal absorption of glucose. Metformin can reduce HbA_{1c} by 1.0 to 1.5% (11 to 16 mmol/mol) and reduce body weight; it also decreases the likelihood of cardiovascular events and death in obese individuals with type 2 diabetes. Since metformin does not increase insulin secretion, it does not increase the risk of hypoglycemia unless it is combined with insulin or insulin secretagogues.

The main adverse effects of metformin are gastrointestinal (bloating, nausea, diarrhea), but starting with a small dose (500 mg once or twice daily with meals) and gradually increasing the dose are effective ways to reduce adverse reactions. Metformin is cleared by renal filtration, so its dose should be limited to no more of 2550 mg/day, and it should not be used if the estimated glomerular filtration rate (eGFR) is less than 30 mL/minute. Metformin also should be temporarily discontinued when individuals undergo angiography with iodinated contrast agents. Metformin may increase the risk of lactic acidosis, and long-term use of metformin has been associated with vitamin B_{12} deficiency and worsening of symptoms of neuropathy, thereby suggesting that periodic testing of the vitamin B_{12} level should be performed in patients on long-term metformin therapy.

Sodium-Glucose Cotransporter 2 Inhibitors

Sodium-glucose cotransporter-2 (SGLT2) inhibitors lower blood glucose by reducing renal reabsorption of glucose at the S1 segment of proximal tubules in the kidney.

This increased urinary loss aids in controlling blood glucose concentrations, lowering body weight by 1 to 3 kg, and reducing blood pressure. SGLT2 inhibitors reduce HbA_{1c} concentrations by approximately 0.5 to 1.0% (5 to 11 mmol/mol) and reduce the risk of major adverse cardiovascular events (including cardiovascular death, acute myocardial infarction, and stroke),[A10,A11] renal events,[A12–A14] and hospitalization rates for heart failure (Chapter 46).[A15,A16] Based on their cardio-renal protective effects, SGLT2 inhibitors are now considered the second drug for type 2 diabetes after metformin in patients who have atherosclerotic cardiovascular disease, heart failure, or chronic kidney disease.

Since SGLT2 inhibitors require glomerular filtration for their glucose-lowering effect, their action diminishes if the eGFR is less than 45 mL/min. Similarly, glycosuria with SGLT2 inhibition is attenuated in patients without hyperglycemia. This primary renal effect of SGLT2 inhibitors is independent of insulin, so the risk of hypoglycemia is small. The weight reduction, which results from the glycosuria, is largely explained by loss of fat mass.

SGLT2 inhibitor-mediated natriuresis and glucosuria lower cardiac preload and reduce pulmonary congestion and systemic edema. SGLT2 inhibitors reduce albuminuria, slow the decline in eGFR, and lower rates of clinically relevant renal events, including progression toward end-stage renal disease (Chapter 109).

SGLT2 inhibitors are associated with an increased risk for genital mycotic infections and urinary tract infections, largely because of the increased urinary excretion of glucose. SGLT2 inhibitors are also associated with increased risk of diabetic ketoacidosis, especially when used in patients with type 1 diabetes but also in type 2 diabetes,[21] because the glucose-lowering effect leads to lower insulin secretion and a subsequent increased intrinsic ketogenesis related to the increased secretion of glucagon and the promotion of lipolysis.

Glucagon-Like Peptide-1 Receptor Agonists

Glucagon-like peptide-1 receptor agonists, which are peptide derivatives of either exendin-4 or human glucagon–like peptide-1, are designed to resist degradation by the enzyme dipeptidyl peptidase 4. These agents bind with specificity to the glucagon-like peptide-1 receptor to stimulate glucose-dependent

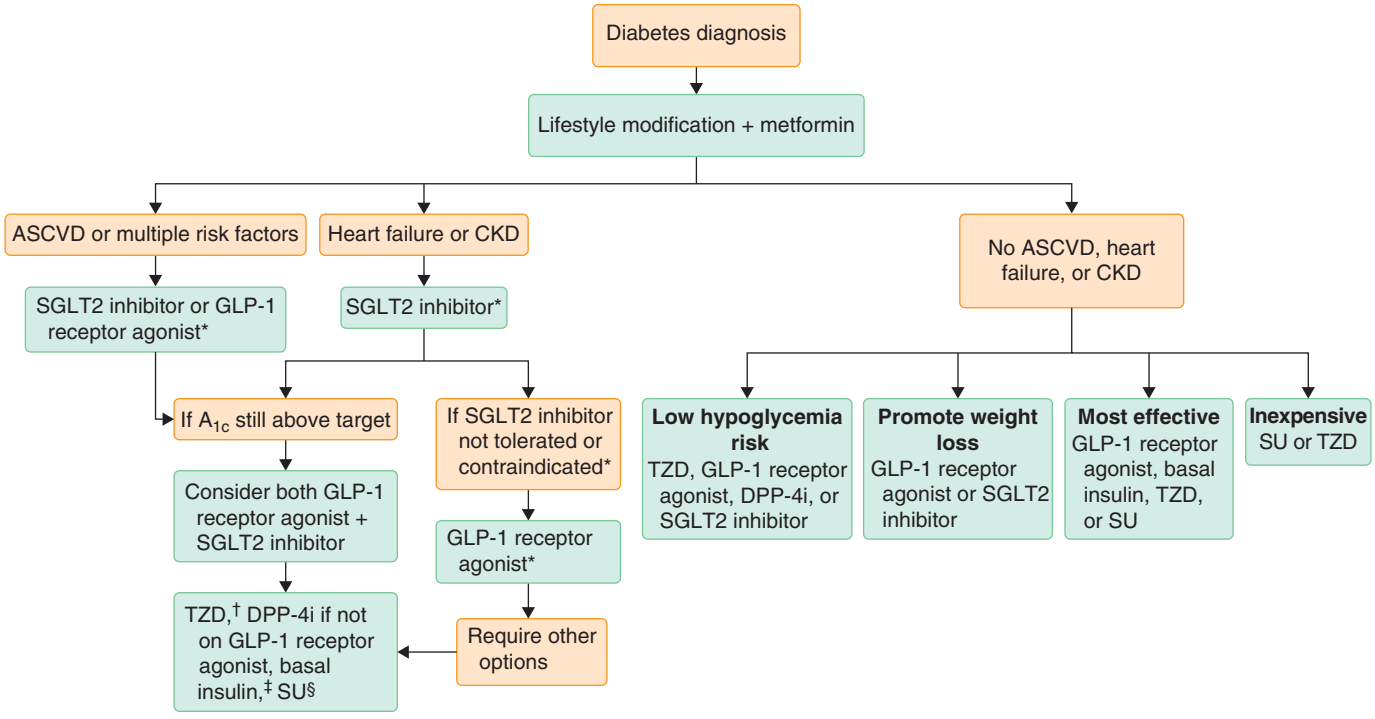

FIGURE 210-3. Algorithm for pharmacologic treatment of type 2 diabetes. *Choose drug with proven benefit for this indication (see text). †Low dose may be better tolerated though less well studied for CVD effects. ‡Degludec and U-100 glargine have demonstrated CVD safety. §Choose later-generation SU to lower risk of hypoglycemia; glimepiride has shown similar cardiovascular safety to DPP-4i. ASCVD = atherosclerotic cardiovascular disease; CKD = chronic kidney disease; CVD = cardiovascular disease; DPP-4 = dipeptidyl peptidase 4; DPP-4-i = DPP-4 inhibitor; GLP-1 = glucagon-like peptide 1; SGLT-2 = sodium-glucose cotransporter-2; SU = sulfonylurea; TZD = thiazolidinedione.

insulin release from the pancreatic β cells. These agents enhance the secretion of insulin and inhibit the secretion of glucagon in a glucose-dependent manner, delay gastric emptying, and reduce food intake via central suppression of appetite. The longer half-life of the newer glucagon-like peptide-1 receptor agonists allows for once-weekly administration.

Compared with placebo, these agents reduce HbA_{1c} by about 1 to 1.2% (11 to 13 mmol/mol). Glucagon-like peptide-1 receptor agonists also reduce body weight by about 6 percentage points in obese individuals with type 2 diabetes,[A17] triglyceride levels, and blood pressure. In people with type 2 diabetes and established cardiovascular disease or multiple cardiovascular risk factors, liraglutide, dulaglutide, and semaglutide significantly reduce the incidence of major adverse cardiovascular events, including acute myocardial infarction, cardiovascular death, and stroke compared with placebo,[A18] and guidelines recommend them in individuals who have a history of cardiovascular disease or major risk factors for it. The risk of hypoglycemia is low with monotherapy but higher when these agents are used in combination with sulfonylureas or insulin. Once-daily oral semaglutide, which is approved in many parts of the world, reduces the HbA_{1c} level (a mean reduction of 0.8 to 1.3% [9 to 14 mmol/mol]) and significantly reduces body weight by 2 to 4 kg compared with placebo[A19] and also reduces cardiovascular events.[A20] As with injectable forms, the oral formulation is associated with significant gastrointestinal adverse events, including nausea, emesis, and diarrhea, which occur mostly in the initial stage of treatment and gradually diminish over time.

Tirzepatide, which is a dual glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1 receptor agonist, is a once-weekly subcutaneous agent that is more effective than pure glucagon-like peptide-1 receptor agonists for weight loss and reducing HbA_{1c} levels.[A21] It is useful as an adjunct to insulin[A22] or instead of insulin in difficult-to-control patients.[A23,A24]

Dipeptidyl Peptidase 4 Inhibitors

Endogenous glucagon-like peptide-1, which is secreted by L cells in the small intestine in response to the presence of food in the gastrointestinal tract, exerts a variety of glucoregulatory effects, including secretion of insulin, inhibition of the release of glucagon, and promotion of satiety. In people with type 2 diabetes, however, the effects of glucagon-like peptide-1 are significantly impaired, thereby greatly reducing the capacity to release insulin in response to the intake of food. Glucagon-like peptide-1 is rapidly degraded by the dipeptidyl peptidase 4 enzyme, thereby resulting in a half-life of less than 2 minutes. By inhibiting the dipeptidyl peptidase 4 enzyme, these inhibitors increase circulating concentrations of endogenous glucagon-like peptide-1, increase the secretion of insulin, and reduce the secretion of glucagon. These agents lower HbA_{1c} by 0.5 to 1.0% (5 to 11 mmol/mol), and their safety profile is generally favorable.

Dipeptidyl peptidase 4 inhibitors can be used as monotherapy when metformin is contraindicated or not tolerated or, more commonly, as add-on therapy (including as fixed-dose combinations; see Table 210-6) either initially or when metformin is insufficient. Dipeptidyl peptidase 4 inhibitors are body weight neutral and can be used in patients with liver failure. They are safe from a cardiovascular perspective; but, unlike SGLT-2 inhibitors and glucagon-like peptide receptor agonists, they do not reduce cardiovascular events.[A25] As a result, they are less preferred than these other two agents. Most agents can be used in persons with impaired renal function, but, except for linagliptin, dose adjustment is needed when used in patients with renal dysfunction (i.e., an eGFR <50 mL/minute/1.73 m^2). Dipeptidyl peptidase 4 inhibitors should be discontinued if a glucagon-like peptide-1 receptor agonist is used.

Second-Line Drugs

Insulin Secretagogues

The main pharmacologic effect of the insulin secretagogues, including the sulfonylureas and the glinides, is to increase insulin concentrations by stimulating the secretion of insulin from pancreatic β cells. These agents bind to the ATP-sensitive potassium channel in the β-cell membrane (see E-Fig. 210-1), thereby resulting in membrane depolarization and, ultimately, release of insulin from preformed secretory granules. Oral sulfonylureas are inexpensive, once- or twice-daily medications that, when used in monotherapy, reduce HbA_{1c} concentrations by 1.0 to 1.5% (11 to 16 mmol/mol). However, they are less effective when they are added to other medications. The main side effect of the sulfonylureas is hypoglycemia, which can be more severe and prolonged than that produced by insulin, particularly when longer-acting formulations such as glyburide/glibenclamide are used in the elderly. They are also associated with weight gain. Sulfonylureas have a primary failure rate of 20% and a secondary failure rate of 5 to 10% per year of treatment, probably due to apoptosis of β cells.[A26]

Thiazolidinediones

Thiazolidinediones decrease blood glucose levels primarily by improving insulin-mediated glucose uptake in peripheral tissues and by reducing the hepatic production of glucose. They bind to a nuclear receptor, peroxisome proliferator-activated receptor γ, and thus regulate the transcription of a variety of genes involved in carbohydrate and lipid metabolism. Thiazolidinediones do not cause hypoglycemia when used alone, but they may increase the risk of low blood glucose when used in combination with insulin or insulin secretagogues.

Thiazolidinediones as monotherapy can decrease HbA_{1c} by about an absolute 1% (11 mmol/mol). They reduce the risk of all-cause mortality, nonfatal myocardial infarction, and stroke in diabetic patients with cardiovascular disease. However, thiazolidinediones are associated with significant weight gain and edema, especially when used in combination with insulin, as well as an increased risk of macular edema and heart failure. Thiazolidinediones are contraindicated in patients who have active liver disease, except they can be useful in patients with nonalcoholic steatohepatitis. Thiazolidinediones also have been linked to osteoporosis and an increased risk of fracture of distal long bones, so they must be used cautiously or not at all in patients who have risk factors for osteoporosis. They also should be avoided in patients who have uninvestigated hematuria.

α-Glucosidase Inhibitors

The α-glucosidase inhibitors (e.g., acarbose and voglibose) reduce postprandial blood glucose by inhibiting the absorption of carbohydrates in the upper small intestine and can be helpful for patients who consume carbohydrates as their main food ingredient and experience postprandial hyperglycemia. In patients who are newly diagnosed with diabetes, acarbose 300 mg/day has a similar hypoglycemic effect to that of metformin 1500 mg/day. Reduction of the absorption of carbohydrates increases the disaccharide load in the colon and may lead to gaseous distention and flatulence that some individuals may tolerate poorly. Starting with a small dose and gradually increasing the dose may reduce this adverse effect. These agents are administered at the beginning of each meal and are contraindicated in patients who have inflammatory bowel disease, partial bowel obstruction, or severe renal or hepatic disease. The risk of hypoglycemia is very low when these agents are used alone, but patients must be instructed to use glucose or honey to correct hypoglycemia because dietary sucrose, complex sugars, and starchy foods will be poorly absorbed.

Insulin

Insulin treatment can be considered for people with type 2 diabetes at any stage but is usually reserved for when other therapies fail. Since progressive pancreatic β-cell failure progressively reduces the secretion of insulin, many, if not most, people who have type 2 diabetes ultimately may require insulin therapy to achieve and maintain adequate glycemic control. In addition, short-term (2 weeks to 3 months) intensive insulin treatment may be helpful when newly diagnosed individuals with type 2 diabetes have a HbA_{1c} 9.0% (75 mmol/mol) or higher with symptomatic hyperglycemia (polyuria, polydipsia, and weight loss). Insulin also is often indicated in critically ill or hospitalized hyperglycemic patients to maintain adequate glycemic control. As with type 1 diabetes, insulin treatment is ideally managed by an endocrinologist or in close collaboration with an endocrinologist in locales where an endocrinologist may not be readily accessible.

In people with uncontrolled type 2 diabetes treated with noninsulin antidiabetic agents, supplemental insulin glargine results in similar improvement in glycemic control but less hypoglycemia compared with NPH insulin. Premixed human insulin also is equally efficacious and is associated with less weight gain and hypoglycemia compared with NPH insulin.

Daily insulin requirements tend to be higher for people with type 2 diabetes compared with type 1 diabetes as a reflection of insulin resistance. Use of concentrated insulin preparations (e.g., U-200 lispro, U-200 degludec, U-300 glargine, U-500 regular) may be helpful in persons who are insulin resistant and require insulin doses exceeding 100 units per day. Once-weekly insulin is currently in development but is not yet licensed. Among patients who have type 2 diabetes and are at high risk for cardiovascular events, degludec reduces hypoglycemic events compared with glargine but is no better for reducing the incidence of major cardiovascular events.[A27]

Bariatric Surgery

Bariatric surgery (Chapter 201) is more successful than medical therapy for people living with severe obesity. In such individuals, it reduces hepatic steatosis and improves glycemic control, blood pressure, lipids, and almost all other cardiovascular risk factors, thereby allowing for medications to be reduced or sometimes even discontinued.[A28] Bariatric surgery also is associated with a reduction in all-cause mortality in patients who have severe obesity.[22] As a result, it should be recommended for such patients.

Metabolic Monitoring

Ongoing assessment of glycemic control is necessary to ensure optimal outcomes in people with type 2 diabetes. Measurement of HbA_{1c}, which reflects mean glucose levels during the preceding 2- to 3-month period, should be performed twice yearly in stable patients but quarterly in persons whose therapy has been recently changed or who are not meeting glycemic goals. Self-monitoring of blood glucose levels, and preferably continuous glucose monitoring,[A29] is recommended for anyone using insulin and may be useful for individuals who are trying to achieve target glucose control.[23]

PREVENTION

Individuals with risk factors for type 2 diabetes, especially individuals who are overweight or obese,[24] should be considered for screening with an HbA_{1c} level or a fasting glucose concentration even though screening has not been proven to reduce subsequent mortality.[A30] Screening will also allow identification of people with prediabetes, who may benefit from preventive interventions (Table 210-7).

Lifestyle intervention stressing modest weight reduction (minimum 7% of body weight) with a reduced fat, hypocaloric diet and moderate-intensity physical activity for 150 minutes/week (http://www.bsc.gwu.edu/dpp/lifestyle/dpp_part.html) can reduce incident diabetes by about 60% over 3 years and about one-third longer term. Successful weight loss is the major predictor of benefit, with every kilogram of weight loss reducing the risk of diabetes by about 15%. Primary care–led weight management programs[A31] and the use of locaserin[A32] can reduce hyperglycemia and lead to remission of type 2 diabetes. Even among individuals who do not lose weight, achieving the physical activity goal can reduce the risk of diabetes. Data also suggest that lowering blood pressure may reduce the onset of type 2 diabetes, with each 5 mm Hg reduction in systolic blood pressure from angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers reducing the risk by about 15% and other medications not helpful.[A33]

Metformin (up to 1 g twice daily) and the α-glucosidase inhibitor acarbose (up to 100 mg three times daily) can reduce the short-term risk of diabetes by about 25%. Liraglutide used at the dose approved for weight loss (3 mg/day) can reduce incident diabetes by about 20% in overweight patients with prediabetes. The thiazolidinediones can prevent or delay the onset of diabetes but are not used for this purpose because of concerns about their long-term safety. Whether these interventions to prevent or delay the onset of diabetes will result in lower rates of microvascular or macrovascular complications remains to be determined. For this reason, none of these drugs is approved by the U.S. Food and Drug Administration to prevent diabetes.

TABLE 210-7 CRITERIA FOR DIABETES SCREENING IN ASYMPTOMATIC ADULTS

1. Overweight or obese (BMI >25 kg/m^2) with one or more of the following:
   - First-degree relative with type 2 diabetes
   - High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
   - History of cardiovascular disease
   - Hypertension
   - HDL cholesterol level <35 mg/dL or triglyceride level >250 mg/dL
   - Women with polycystic ovary syndrome
   - Physical inactivity
   - Other clinical conditions associated with insulin resistance

   Screening should begin at age 45 and be repeated at least every 3 years
2. Patients with prediabetes (HbA_{1c} ≥5.7%, IGT, or IFG) should be tested annually
3. Women with a history of gestational diabetes should be tested at least every 3 years

BMI = body mass index; HDL = high-density lipoprotein; IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

Modified from American Diabetes Association. Standards of care in diabetes—2023. *Diabetes Care.* 2023;46(Suppl 1):S97-S110.

PROGNOSIS

Type 2 diabetes is a chronic and, in most cases, progressive condition with potentially serious health consequences similar to those that affect patients with type 1 diabetes (see later). However, substantial evidence indicates that early intervention with a multifactorial approach to achieve and to maintain metabolic control, combined with aggressive control of cardiovascular risk factors, can substantially reduce the burden of diabetes and improve quality of life. In people who have type 2 diabetes, life expectancy at age 50 years is 6 years lower, on average, than in people without diabetes.

GESTATIONAL DIABETES

Diabetes that appears for the first time during pregnancy and typically regresses after delivery is termed gestational diabetes (Chapter 221). Hyperglycemia is usually detected in the late second trimester (13 to 26 completed weeks of gestation) or in the third trimester (27 to 40 weeks) and resolves following delivery. Gestational diabetes affects approximately 6% of pregnant women in the United States, with a prevalence ranging from 1 to 25% depending on the ethnicity of the mother and the criteria used for the diagnosis. Women who develop gestational diabetes usually have risk factors including overweight or obesity, older age (>30 years), and a family history of type 2 diabetes (see Table 210-5).

Physiologic insulin resistance occurs during pregnancy because the placenta secretes diabetogenic hormones, such as growth hormone, corticotropin-releasing hormone, human placental lactogen, and progesterone. In a normal pregnancy, women have a 60% reduction in insulin sensitivity. In women with normal pancreatic function, the pancreas can compensate by secreting enough insulin to offset this physiologic insulin resistance of pregnancy. The inability to overcome the insulin resistance of pregnancy despite β-cell hyperplasia leads to gestational diabetes. Women who have gestational diabetes are at increased risk of serious perinatal complications, including gestational hypertension, preeclampsia, polyhydramnios, and need for cesarean section.

Offspring born to mothers with gestational diabetes are at increased risk for having fetuses that have large-for-gestational-age birth weights, which increase birth complications, including the risk of congenital malformations, need for cesarean delivery, shoulder dystocia, and birth injury. The risks of spontaneous abortion, fetal demise, neonatal hypoglycemia, and neonatal hyperbilirubinemia are also increased. Intrauterine exposure to diabetes increases the fetus's future risk of developing obesity and type 2 diabetes.[25]

DIAGNOSIS

All pregnant women should be screened for gestational diabetes at 24 to 28 weeks' gestation. Gestational diabetes can be diagnosed with either the one-step or the two-step approach using the oral glucose tolerance test (see Chapter 221).

TREATMENT

Aggressive glycemic control reduces adverse pregnancy outcomes, including macrosomia and traumatic delivery. Women should self-monitor their fasting and postprandial glucose concentrations to achieve glycemic control. Current guidelines recommended targets that women with gestational diabetes target a fasting glucose less than 95 mg/dL (5.3 mmol/L), a 1-hour postprandial glucose level less than 140 mg/dL (7.8 mmol/L), or a 2-hour postprandial glucose less than 120 mg/dL (6.7 mmol/L). Lifestyle intervention, comprising dietary modification, physical activity, and weight management, is essential and is sufficient to achieve blood glucose targets in as many as 70 to 85% of women. If blood glucose targets are not achieved with lifestyle intervention, the addition of glucose-lowering therapy as for type 2 diabetes (see Chapter 221 and earlier in the text) is warranted. Most hypoglycemic medications are contraindicated in pregnancy. Although metformin appears to be preferable to insulin therapy, escalation to insulin is often required.[A34]

PROGNOSIS

For a woman with gestational diabetes, the lifetime odds of developing type 2 diabetes are up to 20 times higher, and nearly 50% of these women will develop impaired glucose metabolism within 10 years of having gestational diabetes.[26] In addition to the higher risk of diabetes, women with a history of gestational diabetes also have a cluster of cardiovascular disease risk factors such as obesity, hypertension, and dyslipidemia.

ACUTE ISSUES FOR INDIVIDUALS WITH DIABETES

INPATIENT MANAGEMENT OF DIABETES

During hospitalization, both hyperglycemia and hypoglycemia are associated with adverse outcomes. Most people who have type 1 diabetes and who are well enough to do so can be managed with their usual insulin injection regimen during hospitalization, but extra attention should be paid to the risk of hypoglycemia because of missed or delayed meals.[27] Insulin pump therapy can be continued during hospitalization if the individual is able to direct its use and hospital personnel are sufficiently familiar with this form of treatment.

For non–critically ill hospitalized patients with type 2 diabetes, chronic diabetes medications may need to be altered. Subcutaneous insulin is preferred to maintain a fasting glucose concentration target below 140 mg/dL (7.8 mmol/L) and a random or postprandial glucose concentration to below 180 mg/dL (10 mmol/L), if these goals can be achieved with a minimal risk of hypoglycemia. Basal insulin (see Table 210-4) is sufficient for many people with type 2 diabetes, but some may require additional prandial or corrective doses of short-acting insulin.

For critically ill people with type 1 and type 2 diabetes, intensive glucose control can be harmful, particularly when it is accompanied by hypoglycemia. For critically ill patients in intensive care settings, a variable-rate intravenous insulin infusion should be titrated to maintain the plasma glucose concentration between 140 and 180 mg/dL (7.8 to 10.0 mmol/L).

Prolonged dependence on subcutaneous or variable rate intravenous insulin infusions ("sliding scales") should be avoided because of the increased risk of hypoglycemia. Persons with type 1 diabetes should return to their usual outpatient doses of insulin as soon as they are eating and drinking normally. For individuals who have with stable type 2 diabetes and who are eating consistent meals and for patients who are nearing hospital discharge, resumption of their usual oral or noninsulin injectable medications can also be considered, assuming that their preadmission glycemic control was adequate. However, the safety of SGLT2 inhibitors in inpatients remains unknown.

HYPOGLYCEMIA

EPIDEMIOLOGY

Hypoglycemia (Chapter 211), which in diabetes is always iatrogenic or due to accidental or intentional overdose, is the most frequent and serious adverse effect of insulin therapy,[28] especially in type 1 diabetes in which it accounts for about 2 to 6% of all deaths. On average, people with type 1 diabetes experience two episodes of symptomatic hypoglycemia per week and one episode of temporarily severe (i.e., requiring third-party assistance) hypoglycemia per year. Risk factors for hypoglycemia (Table 210-8) include strict glycemic control, exercise, and a mismatch between carbohydrate intake and the insulin dose.

Episodes of severe hypoglycemia also become progressively more common in people with a longer duration of type 2 diabetes, due in part to progressive β-cell failure and increased dependence on pharmacologic treatments. These risks are especially pronounced when sulphonylureas or insulin are being used aggressively in an attempt to achieve inappropriately tight glycemic control. Antidiabetic agents such as metformin, the thiazolidinediones, and incretin-based drugs (dipeptidyl peptidase-4 inhibitors, glucagon-like peptide-1 and glucagon-like peptide/gastric inhibitory polypeptide receptor agonists) are associated with measurable, albeit low, risks of hypoglycemia, but symptomatic hypoglycemia is rare unless these drugs are used in combination with insulin or sulfonylureas. The elderly are at particularly high risk for iatrogenic hypoglycemia because the intensity of reactive adrenergic symptoms may be reduced, so the degree of hypoglycemia-induced cognitive impairment may be greater.

PATHOBIOLOGY

Iatrogenic hypoglycemia usually occurs when a mismatch between insulin concentrations and carbohydrate intake develops, usually in the presence of a compromised counter-regulatory physiologic defense against a falling plasma glucose concentration. The dose of the insulin secretagogue or insulin itself may not be excessive, but factors such as missed meals, exercise, recent weight loss, or alcohol may lead to a fall in the plasma glucose concentration. Conventional risk factors for hypoglycemia include inadequate caloric consumption (skipped or delayed meals, malnutrition), increased insulin sensitivity (weight loss, exercise, medications), impaired glucose production (alcohol intake, liver, or renal disease), or decreased insulin clearance (renal failure).

In people with type 1 diabetes, the release of counter-regulatory hormones (catecholamines and glucagon) to stimulate hepatic glycogenolysis and gluconeogenesis in the liver and kidney in response to low glucose levels becomes sluggish and even defective over time. People who have recurrent hypoglycemic episodes, especially patients with liver disease or alcohol use disorder, may have insufficient liver glycogen to mount a gluconeogenic response in the face of rising concentrations of counter-regulatory hormones. Furthermore, in people with type 1 diabetes, the release of glucagon during hypoglycemia may become impaired shortly after the onset of diabetes. The release of epinephrine during hypoglycemia also becomes progressively defective. This

TABLE 210-8 RISK FACTORS FOR HYPOGLYCEMIA

Medical issues
- Strict glycemic control
- Previous history of severe hypoglycemia
- Long duration of type 1 diabetes
- Duration of insulin therapy in type 2 diabetes
- Lipohypertrophy at injection sites
- Impaired awareness of hypoglycemia
- Severe hepatic dysfunction
- Impaired renal function (including patients on dialysis)
- Sepsis
- Inadequate treatment of previous hypoglycemia
- Terminal illness
- Cognitive dysfunction/dementia
- C-peptide negativity

Lifestyle issues
- Increased exercise (relative to usual)
- Increasing age
- Alcohol
- Early pregnancy
- Breast-feeding
- No or inadequate blood glucose monitoring

Reduced carbohydrate intake/absorption
- Food malabsorption (e.g., gastroenteritis, celiac disease, gastroparesis)
- Bariatric surgery involving bowel resection

Endocrine disorders
- Hypoadrenalism
- Growth hormone deficiency
- Hypothyroidism
- Hypopituitarism

TABLE 210-9 THE EDINBURGH HYPOGLYCEMIA SCALE

AUTONOMIC	NEUROGLYCOPENIC	GENERAL MALAISE
• Sweating • Palpitations • Shaking • Hunger	• Confusion • Drowsiness • Odd behavior • Speech difficulty • Incoordination	• Headache • Nausea

decrease in the epinephrine response during hypoglycemia is accompanied by an attenuated autonomic neural response, which results in the clinical syndrome of impaired awareness of hypoglycemia. In the absence of autonomic symptoms, mild hypoglycemia may proceed unnoticed, without the usual warning signs that would alert an individual to a falling glucose level. In this vicious cycle, hypoglycemia begets hypoglycemia and an increased risk for severe hypoglycemia.

CLINICAL MANIFESTATIONS

The normal counter-regulatory response to hypoglycemia results in typical adrenergic and neuroglycopenic hypoglycemia symptoms (Table 210-9). Should the glucose level continue to drop, then the individual may become progressively more confused, eventually lose consciousness, have seizures, and may die. Cardiovascular consequences may include cardiac arrhythmias, prolongation of the QTc interval, repolarization abnormalities, and abnormalities in coagulation and inflammation, with an increased risk of atherosclerotic and vascular events, including acute myocardial infarction and stroke.

Hypoglycemia (Chapter 211) affects the daily lives of persons with diabetes and can have a dramatic effect on quality of life. It can induce great fear, preclude comfortable engagement in routine activities (e.g., driving, uninterrupted sleep), and lead the person with diabetes and their clinician to set higher glycemic targets, limit treatment, particularly with insulin, and hence accept poorer metabolic control. If prolonged, this undertreatment can increase the risk of other diabetes complications.

Nocturnal hypoglycemia (or hypoglycemia during sleep at any time) may be asymptomatic and unsuspected because the plasma glucose concentration is rarely measured during the night unless using a continuous glucose monitor. Some people with nocturnal hypoglycemia present with sleep disturbances, morning headache, chronic fatigue, or depression. Risk factors for nocturnal hypoglycemia include increased physical activity in the previous 24 hours, certain insulin regimens (e.g., use of NPH or regular insulin leads to a higher risk compared with the short- or long-acting insulin analogues), meal content (e.g., higher fat content leads to slower gut transit time, thereby increasing the risk of hypoglycemia), and alcohol consumption (alcohol prevents glycogenolysis, thereby increasing the risk of hypoglycemia). In addition, sleep is associated with a decrease in the autonomic response to hypoglycemia.

DIAGNOSIS

The threshold plasma glucose value that results in hypoglycemic symptoms is not constant; it is lower after recent antecedent hypoglycemia and higher in persons with poor glycemic control. Furthermore, the same individual may experience symptoms at different glucose concentrations depending on what they are doing. However, a self-monitored glucose of 70 mg/dL (3.9 mmol/L) or less should alert the person with diabetes or their caregiver, regardless of the presence of symptoms.

Iatrogenic hypoglycemia can be severe, documented but not severe, asymptomatic, or pseudo-hypoglycemia (Table 210-10). However, these distinctions are not always clear in clinical practice, where the severity of symptoms is often discordant with the severity of hypoglycemia. An individual may feel intense symptoms of hypoglycemia at a glucose concentration of 50 to 60 mg/dL (2.8 to 3.3 mmol/L), for which there is no evidence of cognitive impairment or imminent danger, whereas potentially dangerous plasma glucose concentrations in the range of 20 to 40 mg/dL (1.1 to 2.2 mmol/L) might go unappreciated owing to lack of classical symptoms. The only practical approach to detecting nocturnal hypoglycemia is regular nocturnal (3 AM) self-monitoring or the use of continuous glucose monitors with alarm features.

TREATMENT

At the time of their initial diagnosis, people with diabetes must be educated about the symptoms of hypoglycemia, its predisposing factors, and how to treat it. As the disease progresses, people with diabetes must be informed that the typical sympathoadrenal symptoms may diminish over time. Recurrent symptoms of potential hypoglycemia should be carefully evaluated, and possibly unrecognized events (e.g., unexplained night sweats or a clouded mental state in the morning that could be caused by nocturnal hypoglycemia) must be evaluated. If adults are conscious and able to swallow, the best approach is 15 to 20 g of rapid-acting carbohydrate in the form of dextrose tablets, 150 to 200 mL of fresh fruit juice, or 3 to 4 heaped teaspoons of sugar dissolved in water. Foods with a high fat content (e.g., chocolate) should be avoided because they delay gastric emptying, thereby slowing the absorption of carbohydrate. If the capillary glucose remains less than 72 mg/dL (4.0 mmol/L), oral treatment can be repeated up to three times, 15 minutes apart. If the glucose remains low, the individual requires formal medical attention for intramuscular glucagon or intravenous glucose. Once the glucose level has risen and the person has recovered, a longer-acting carbohydrate should be given (e.g., a slice of bread, 200 to 300 mL of cow's milk, or their next meal if it is due). The next insulin dose should not be omitted but may need to be adjusted.

For patients who can swallow but who are confused, disorientated, or poorly cooperative, the same oral measures can be tried, but an alternative is to squeeze 2 tubes of 40% dextrose gel between the mouth and the gums for rapid absorption.[29] However, intramuscular glucagon or intravenous dextrose may be necessary, especially if the patient is unconscious, having seizures, or aggressively refusing treatment. Basic life support (Chapter 50) may be emergently required.

TABLE 210-10 CLASSIFICATION OF IATROGENIC HYPOGLYCEMIA IN PEOPLE WITH TREATED DIABETES

	CLINICAL FEATURES
Severe hypoglycemia	Any episode, regardless of glucose concentration, with neurocognitive impairment that *requires* third-party assistance to treat.
Documented symptomatic hypoglycemia	Measured glucose concentration ≤70 mg/dL (3.9 mmol/L) that coincides with sympathoadrenal or neurologic symptoms. The episode is self-managed by the person with diabetes.
Asymptomatic hypoglycemia	Measured glucose concentration ≤70 mg/dL (3.9 mmol/L) but without concomitant symptoms. Absence of symptoms may be due to hypoglycemia unawareness or hypoglycemia-associated autonomic failure.
Pseudo-hypoglycemia	Typical hypoglycemia symptoms, but with measured glucose concentrations >70 mg/dL (3.9 mmol/L). Symptoms may be caused by resetting of counter-regulatory system in the setting of chronic suboptimal glucose control.

PREVENTION

In addition to educating the individual with diabetes about the risks, signs, and symptoms of hypoglycemia and potentially adjusting their medication doses, strategies to prevent nocturnal hypoglycemia include eating "long-acting" bedtime snacks (slowly absorbed carbohydrate, such as uncooked cornstarch) and regular monitoring of blood glucose concentration at bedtime so that corrective action (carbohydrate ingestion) can be taken. The use of newer, ultra-long-acting insulin formulations may also help mitigate the risk.

PROGNOSIS

An episode of severe hypoglycemia can be the immediate cause of death in people with type 1 diabetes, with reported mortality rates ranging from 4 to 10%. Mortality rates increase with increasing frequency of severe events. Prolonged episodes of very low circulating glucose (<15 mg/dL [0.8 mmol/L]) can themselves cause significant brain damage, but death due to fatal hypoglycemia may be the result of other mechanisms, such as ventricular arrhythmias precipitated by large catecholamine surges and concurrent electrolyte disturbances. Many motor vehicle licensing authorities will rescind an individual's driving license if they have hypoglycemic unawareness or have two or more episodes of severe daytime hypoglycemia in any 12-month period.

ACUTE HYPERGLYCEMIC STATES

EPIDEMIOLOGY

Diabetic ketoacidosis (DKA) and the hyperosmolar hyperglycemic state, which are the most serious acute hyperglycemic complications of diabetes, are part of the same pathophysiologic spectrum. The global incidence of diabetic ketoacidosis varies between 8.0 and 50 cases per 1000 people with type 1 diabetes per year, although it has been reported to be as high as 260 per 1000 people in China. The incidence of hyperosmolar hyperglycemic state is very difficult to estimate because of the absence of a universal definition of the condition and because it often occurs together with diabetic ketoacidosis.

Diabetic ketoacidosis is most frequently associated with type 1 diabetes, but it may also occur in type 2 diabetes under conditions of extreme stress, such as a major infection or trauma. Ketosis-prone type 2 diabetes most frequently occurs in people of African or Hispanic origin.

The condition formerly known as the hyperglycemic hyperosmolar nonketotic state or coma has been renamed the hyperosmolar hyperglycemic syndrome to highlight two important points: ketosis (and acidosis) may be present to varying degrees in hyperosmolar hyperglycemic syndrome, and alterations in sensorium most commonly occur in the absence of coma. Hyperosmolar hyperglycemic syndrome typically occurs in people with type 2 diabetes, but some affected individuals may present with ketosis and acidosis.[30] Major risk factors for hyperosmolar hyperglycemic syndrome include (but are not limited to) older age (most cases occur in people ages 65 years and older), use of medications that alter carbohydrate metabolism (e.g., glucocorticoids), intercurrent illness, and impaired cognition (i.e., impaired ability to recognize thirst or to obtain access to water).

PATHOBIOLOGY

Diabetic ketoacidosis and hyperosmolar hyperglycemic state are commonly precipitated by an acute event, which may be as simple as nonadherence with insulin therapy or a major systemic infection (Table 210-11).

Diabetic Ketoacidosis

The three fundamental biochemical features of diabetic ketoacidosis are hyperglycemia or a history of diabetes (the "D"), urinary ketone levels of 2+ or more or 3.0 mmol/L or more (the "K"), and an arterial or venous pH of less than 7.3 (the "A"). These biochemical abnormalities result from the combined effects of deficient circulating insulin and an excess of counterregulatory hormones. This hormonal milieu promotes the delivery of substrates from muscle (amino acids, lactate, and pyruvate) and adipose tissue (free fatty acids, glycerol) to the liver, where they are converted to glucose or to ketone bodies (β-hydroxybutyrate, acetoacetate, acetone). Glucose and ketones are released into the circulation at greater rates than their utilization. The hyperglycemia leads to an osmotic diuresis that promotes dehydration and loss of electrolytes. Fluid depletion leads to hemoconcentration, which further exacerbates hyperglycemia and hyperosmolality.

TABLE 210-11 THE MOST COMMON PRECIPITANTS OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC STATE

MOST COMMON
Infections
Inadequate insulin treatment or nonadherence
New-onset diabetes
Acute coronary syndrome
Unknown
OTHER PRECIPITATING FACTORS
Intercurrent illness, including (but not limited to):
Cerebrovascular accident
Acute pulmonary embolism
Acute pancreatitis
Intestinal or mesenteric thrombosis
Alcohol intoxication
Endocrinopathies:
Cushing syndrome
Thyrotoxicosis
Acromegaly
Severe burns
Hyperthermia or hypothermia
Drugs:
Corticosteroids
Clozapine
Olanzapine
Cocaine
Lithium
Sympathomimetics
Thiazide diuretics
Sodium-glucose cotransporter-2 inhibitors

Hyperosmolar Hyperglycemic State

Severe hyperglycemia can cause a hyperosmolar state because people with diabetes, particularly the elderly or physically infirm, cannot consume enough liquid to keep pace with a significant glucose-induced osmotic diuresis. The resulting hemoconcentration and prerenal renal impairment eventually further reduce glucose excretion by the kidney. In contrast to diabetic ketoacidosis, severe acidosis and ketosis are usually absent even though glucose concentrations are generally higher, probably because enough residual insulin is available to suppress lipolysis and to avoid significant production of ketones. Some people who have type 2 diabetes and who have depressed endogenous insulin secretion may be unable to suppress ketone production fully in the face of elevated counter-regulatory hormones produced by physical illness and, as a result, present with a mixed picture of hyperosmolar hyperglycemic state and diabetic ketoacidosis. However, because people with hyperosmolar hyperglycemic state have higher portal vein insulin concentrations than do patients with diabetic ketoacidosis, the production of ketones by the liver is quantitatively less, thereby causing only mild acidosis. In the hyperosmolar hyperglycemic state in the absence of concurrent acid-base disturbances, the arterial pH rarely drops below 7.30, and serum bicarbonate levels typically do not fall below 18 mmol/L.

CLINICAL MANIFESTATIONS

The most notable findings in both diabetic ketoacidosis and the hyperglycemic hyperosmolar state are usually a variety of often reversible neurologic abnormalities. Common manifestations include a reduced Glasgow Coma Score (see Table 368-1), extensor plantar reflexes, aphasia, hemisensory or motor deficits, and worsening of a preexisting organic mental syndrome.

Diabetic Ketoacidosis

Diabetic ketoacidosis may signal the onset of type 1 diabetes, especially in the developing world and in infants and very young children. Otherwise, however, diabetic ketoacidosis is more frequently seen when people with established diabetes are poorly adherent to therapy or develop an intercurrent illness. For example, the person with diabetes may be unable to maintain adequate hydration during an illness, such as a viral gastroenteritis, and may mistakenly omit insulin because of an inability to eat. Behavioral factors may also be involved; some younger people may omit insulin deliberately to promote weight loss or to call attention to a dysfunctional home situation.

The clinical history of diabetic ketoacidosis typically involves deterioration during several hours to days, with progressive polyuria, polydipsia, and other symptoms of hyperglycemia. Other common clinical features are weakness, lethargy, nausea, and anorexia. Nonspecific upper abdominal pain can mimic an acute abdomen. Reduced motility of the gastrointestinal tract or, in severe cases, paralytic ileus may further contribute to diagnostic confusion. Physical findings, which are mainly secondary to dehydration, hyperosmolality, and acidosis, include dry skin and mucous membranes, reduced jugular venous pressure, tachycardia, orthostatic hypotension, depressed mental function sometimes with frank coma, and deep, rapid respirations (Kussmaul breathing).

Hyperosmolar Hyperglycemic State

In the hyperosmolar hyperglycemic state, the clinical severity and levels of consciousness generally correlate with the severity and duration of hyperosmolarity. Up to 10% of patients with the hyperosmolar hyperglycemic state present with frank coma, and an equal percentage show no signs whatsoever of mental status change. Gastrointestinal symptoms are seen less frequently than in diabetic ketoacidosis, although a diarrhea-causing illness may be the precipitating event.

DIAGNOSIS

Diabetic Ketoacidosis

The diagnosis of diabetic ketoacidosis is based on the presence of hyperglycemia, ketosis, and acidosis (Table 210-12). Glucose concentrations may vary from normal to more than 1000 mg/dL (55.5 mmol/L), the serum bicarbonate concentration drops below 18 mmol/L, and an excess anion gap is generally proportional to the decrease in the serum bicarbonate level. Hyperchloremia may be superimposed if the individual maintains an adequate GFR and is

able to exchange ketoacids for chloride in the kidney or if the person is given large volumes of 0.9% sodium chloride solution as part of their treatment. The degree of depression of arterial pH depends largely on the degree of respiratory compensation. In mild cases, the pH may range from 7.20 to 7.30; in severe cases, it can fall below 7.00. On occasion, a degree of superimposed metabolic alkalosis (e.g., caused by vomiting or diuretic use) may obscure the true severity of the ketoacidosis; an anion gap out of proportion to the fall of bicarbonate should suggest this possibility. Other common laboratory abnormalities include a reduced measured serum sodium concentration (due to hyperosmolarity and the resulting osmotic shift of intracellular water into the intravascular space) and prerenal kidney impairment. The hemoglobin concentration and hematocrit are typically elevated as a reflection of hemoconcentration. The blood concentrations of potassium, phosphate, and magnesium may be normal, elevated, or reduced when diabetic ketoacidosis is diagnosed, but large total-body deficits of these electrolytes invariably accompany the osmotic diuresis and become readily apparent during treatment. The white blood cell count is typically elevated, sometimes as a result of the metabolic acidosis itself and not necessarily of the presence of infection. An elevated serum amylase level is usually of non-pancreatic origin and can lead to an erroneous diagnosis of pancreatitis.

Special care should be taken in interpreting the results of testing for serum or urine ketones. The rapid diagnosis of diabetic ketoacidosis usually requires qualitative assessment of serum ketones using serum dilutions and reagent strips, which depend on a nitroprusside reaction with acetoacetate. However, acetone reacts weakly with nitroprusside, and β-hydroxybutyrate does not react at all; as a result, the results of qualitative testing for ketones can be misleadingly low. Furthermore, because of the presence of intracellular acidosis, β-hydroxybutyrate levels are often much higher than acetoacetate levels, which may further conceal the true degree of ketoacidosis. Conversely, after insulin therapy is begun, the nitroprusside reaction may give the false impression of sustained ketoacidosis for hours or even days because the nonacidic acetone is slowly cleared from the circulation and because, as acidosis improves, β-hydroxybutyrate is converted to acetoacetate, thereby giving the false impression that ketosis is worsening. As technology has improved, however, bedside capillary ketone monitors are increasingly being used in many parts of the world to help guide the management of diabetic ketoacidosis.

Hyperosmolar Hypoglycemic State

The hyperosmolar hyperglycemic state has no formal definition, but is generally diagnosed when the blood glucose level is greater than 600 mg/dL (33.3 mmol/L), the pH is greater than 7.3 (and/or the serum bicarbonate is >18 mmol/L), and the serum osmolality is greater than 320 mOsmol/L.[31] Significant elevations in blood glucose, which sometimes exceed 1000 mg/dL (55.6 mmol/L), are typical. The laboratory picture is dominated by the effects of uncontrolled hyperglycemia and dehydration; renal function is usually impaired, the hemoglobin concentration and hematocrit are elevated, and liver function tests may be abnormal because of baseline hepatic steatosis. Although severe hyperglycemia would be expected to lower measured serum sodium concentration, a normal or even elevated sodium level may be noted because of the severity of dehydration.

TREATMENT

For the initial management of both diabetic ketoacidosis and hyperosmolar hyperglycemic state, the restoration of circulating volume with adequate tissue perfusion is paramount. Fluid losses of 5 to 10 liters, sodium losses of 5 to 10 mmol/kg, and potassium losses up to 7 mmol/kg are common, and fluid losses may be greater in hyperosmolar hyperglycemic state. Given the volumes of fluid and electrolytes required, patients typically require admission to an intermediate care or intensive care unit where continuous cardiac monitoring is available. In addition to correction of fluid and electrolyte imbalances and administration of insulin, treatment must also include prompt recognition and treatment for any precipitating illness or event (see Table 210-11).

Initial treatment is fluid replacement with 0.9% sodium chloride solution, even if the serum osmolality is high because 0.9% sodium chloride is still relatively hypotonic. The rate of fluid replacement should be 2 to 4 liters in the first 2 to 4 hours in diabetic ketoacidosis but somewhat slower in hyperosmolar hyperglycemic state depending on associated (sometimes precipitating) comorbid conditions, such as ischemic heart disease, heart failure, or renal impairment. In hyperosmolar hyperglycemic state, the serum sodium level may rise as the serum glucose level declines, but overall osmolality will nevertheless be declining, so the infusion should not be changed to 0.45% sodium chloride solution.

A low initial potassium suggests profound total body potassium losses and requires prompt intravenous replacement. Even when the serum potassium is elevated on the initial presentation of diabetic ketoacidosis owing to the metabolic acidosis, it quickly declines after insulin treatment is begun. Potassium replacement should not be prescribed if the serum potassium level remains above 5.5 mEq/L (mmol/L). However, 0.9% sodium chloride solution with potassium 40 mEq/L (ready-mixed) should be administered if the serum potassium level is below 5.5 mEq/L and the person is passing urine. If the serum potassium level falls below 3.5 mEq/L, the potassium regimen needs review. Where the fluid balance permits, an increase in the rate of the infusion of 0.9% sodium chloride solution with potassium 40 mEq/L is possible.

In diabetic ketoacidosis, a fixed-rate intravenous insulin infusion should start at 0.1 units/kg/hour as soon as the diagnosis is made. Once the blood glucose level falls to 250 mg/dL (13.9 mmol/L) and the ketones have fallen to less than 1.0 mmol/L, the insulin infusion rate may be reduced to 0.05 units/kg/hour to prevent hypoglycemia and hypokalemia. In hyperosmolar hyperglycemic state, intravenous fluid alone is the treatment of choice and will result in an initial decline in the glucose level because of increased absolute glycosuria. When the glucose level stops dropping, a fixed-rate intravenous insulin infusion should start at 0.05 units/kg/hour. If the individual was already on a background subcutaneous long-acting insulin, the dose should be continued along with the intravenous insulin. The intravenous insulin infusion should be titrated until the patient can eat, at which time they can resume their usual diabetes regimen, with a 1- to 2-hour overlap between the administration of the subcutaneous insulin dose and the discontinuation of intravenous insulin so as to avoid rebound ketosis. Once glucose concentrations have fallen to less than 250 mg/dL (13.9 mmol/L), 10% dextrose should be added to the fluid replacement regimen. The 0.9% sodium chloride solution acts as the resuscitation fluid, and the 10% dextrose provides a substrate for the insulin infusion.

Bicarbonate replacement is not usually advocated because of the risk of paradoxically worsening the pH in the central nervous system and because restoration of circulating volume and peripheral tissue perfusion is often sufficient to allow pH to rise. Bicarbonate administration should be considered only if the patient is not responding to intravenous insulin and fluids and remains profoundly acidotic (e.g., pH <7.0). Phosphate and magnesium levels should be measured and monitored, but intravenous replacement is not usually recommended unless the phosphate level falls below 1.0 mg/dL and the patient develops profound muscle weakness or other complications.

TABLE 210-12 DIAGNOSTIC CRITERIA FOR DIABETIC KETOACIDOSIS

SEVERITY	GLUCOSE IN MG/DL (MMOL/L)	ARTERIAL OR VENOUS PH	BICARBONATE (MMOL/L)	URINE OR SERUM KETONES	B-HYDROXY BUTYRATE (MMOL/L)	ANION GAP (MMOL/L)	MENTAL STATUS
AMERICAN DIABETES ASSOCIATION CRITERIA FOR ADULTS							
Mild	>250 (13.8)	7.25-7.30	15–18	Positive	>3.0	>10	Alert
Moderate	>250 (13.8)	7.24-7.0	10–15	Positive	>3.0	>12	Alert/drowsy
Severe	>250 (13.8)	<7.0	<10	Positive	>3.0	>12	Stupor/coma

PREVENTION

Education as to why the episode occurred and what the individual can do to prevent a recurrence is critical. Patients who have been admitted with diabetic ketoacidosis or the hyperosmolar hyperglycemic state should see a diabetes educator, specialist nurse, or diabetes doctor during their hospital admission or very soon afterwards. A key component of a diabetes treatment program is education in "sick-day rules" focused on home-based prevention of diabetic ketoacidosis (e.g., frequent blood glucose monitoring, serum or urine ketone testing, intake of small but frequent carbohydrate-containing fluids, and an increased insulin requirement with small doses taken often).

PROGNOSIS

Despite aggressive treatment, mortality rates remain about 4% for diabetic ketoacidosis and up to 20% for the hyperosmolar hyperglycemic state.[32,33] Mortality is associated not only with the extremes of age (i.e., the very young and the elderly) and comorbid conditions but also with the severity of the precipitating illness or event.

CHRONIC MICROVASCULAR COMPLICATIONS OF DIABETES

EPIDEMIOLOGY

The major clinical burden associated with long-standing diabetes is the development of vascular disease, which includes characteristic microvascular complications (retinopathy, nephropathy, neuropathy) and accelerated medium- and large-vessel atherosclerosis. Complications typically develop at a younger age in people with type 1 diabetes, but the same complications also can occur in people with type 2 diabetes. Diabetes, which is the seventh leading cause of death in the United States excluding coronavirus disease 2019, is the leading cause of kidney failure (Chapter 117), nontraumatic lower limb amputations (Chapter 65), and new cases of blindness (Chapter 391) among adults in the United States. Diabetes is also a major cause of coronary heart disease (Chapter 39), heart failure (Chapter 45), and stroke (Chapter 375). The microvascular complications are directly linked, and both the duration and degree of hyperglycemia and better control of diabetes as soon as it is diagnosed reduce the risks. Other factors, including genetic susceptibility, smoking, and concomitant conditions such as hypertension, also contribute to the risk of complications.

PATHOBIOLOGY

The complex cellular and molecular mechanisms that mediate hyperglycemic tissue damage are largely related to oxidative stress and vascular damage. Levels of advanced glycation end products, which are a heterogeneous group of compounds that form from the nonenzymatic interaction of glucose with amino groups on proteins, correlate with diabetes-related vascular complications and mean glucose levels over time. Advanced glycation end products can alter the properties and function of long-lived proteins, such as collagen and elastin, thereby leading to vascular stiffness and increases in the thickness of basement membranes. Advanced glycation end products also bind to specific cell surface receptors, particularly on macrophages and endothelial cells, thereby stimulating activation of signaling cascades that promote inflammation and oxidative stress.

Intracellular hyperglycemia leads to increased de novo synthesis of diacylglycerol, which is a major activator of the protein kinase C family of enzymes, which alter gene expression and result in enhanced angiogenesis, vasoconstriction, vascular permeability (by increases in vascular endothelial growth factor), activation of cytokines, and expansion of the extracellular matrix. In the setting of hyperglycemia and excess fatty acid oxidation, increased flux of glucose through the hexosamine pathway leads to increases in glucosamine 6-phosphate and ultimately post-translational modification of cytoplasmic and nuclear proteins associated with transforming growth factor (α and β1), plasminogen activator inhibitor–1, and endothelial nitric oxide synthase.

MICROVASCULAR COMPLICATIONS

DIABETES-RELATED EYE CONDITIONS

Diabetic retinopathy (Chapter 391) is a highly prevalent, pathognomonic, microvascular complication that eventually affects more than 50% of people with long-term diabetes, although it impairs vision less frequently, especially as the control of glucose levels and blood pressure has improved. Changes include the loss of retinal supporting cells (pericytes), thickening of the basement membrane, and changes in retinal blood flow. Damaged retinal capillaries leak protein, red blood cells, and lipids, thereby leading to retinal edema. Chronic retinal hypoxia (due to capillary occlusion) promotes neovascularization; these new vessels are abnormal and prone to rupture.

TABLE 210-13 CLASSIFICATION OF DIABETIC RETINOPATHY

	CLINICAL FEATURES
Mild NPDR	At least one microaneurysm
Moderate NPDR	Microaneurysms, intraretinal (blot) hemorrhage, soft exudates, venous beading, intraretinal microvascular abnormalities
Severe NPDR	More extensive intraretinal hemorrhages (>20 in each of four quadrants) *or* venous beading in at least two quadrants *or* prominent intraretinal microvascular abnormalities
PDR	Neovascularization and/or vitreous or pre-retinal hemorrhage; traction retinal detachment
Clinically significant macular edema	Retinal thickening or hard exudates approaching or involving the center of the macula

NPDR = nonproliferative diabetic retinopathy; PDR = proliferative diabetic retinopathy.

CLINICAL MANIFESTATIONS

Transient osmotically induced refractive error is common, especially when diabetes is first diagnosed or when glucose levels are high, but it resolves with improving glucose control. Diabetic retinopathy is largely asymptomatic even with severe proliferative retinopathy. However, retinal hemorrhage, inflammation, and scarring can cause diminished visual acuity and can ultimately lead to traction retinal detachment and permanent loss of vision (Table 210-13). Age-related eye conditions, such as cataracts and glaucoma, tend to occur at younger ages among people with diabetes. Diplopia and other gaze disorders due to acute mononeuropathy involving the cranial nerves (typically III or VI) are also more common in diabetes.

Regular screening by an eye care specialist (an ophthalmologist or optometrist) is recommended for all people with diabetes because significant and potentially vision-threatening retinopathy can be present in the absence of any symptoms. Screening should begin when type 2 diabetes is diagnosed (because hyperglycemia has typically been present for years before it is recognized clinically) and at 5 years after type 1 diabetes is diagnosed.

DIAGNOSIS

Early signs of diabetic retinopathy include the presence of microaneurysms, exudates, and intraretinal hemorrhages on funduscopic evaluation (see Figs. 391-22 and 391-23). Additional tests, including fluorescein angiography and ocular coherence tomography, are helpful to detect abnormal vessel permeability and macular edema, which can threaten vision.

TREATMENT AND PREVENTION

Treatment of diabetic retinopathy (Chapter 391) includes laser photocoagulation, which can ablate abnormal vessels (thereby reducing the risk of hemorrhage) and treat macular edema,[34] or the equivalently successful use of anti-VEGF monoclonal antibodies (e.g., ranibizumab).[A35] Vitrectomy can remove hemorrhage and scar tissue that is obscuring vision.

Intensive glycemic control can prevent diabetic retinopathy, delay its progression, and reduce the long-term need for ocular surgery.[A36] However, glycemic control has limited effects on advanced retinal disease. Blood pressure (Chapter 64) control is also important to prevent worsening of retinopathy, and evidence suggests that renin-angiotensin system blockers may be especially beneficial.

PROGNOSIS

The prognosis for diabetic retinopathy is highly dependent on early detection. With early detection, glycemic control, and optimization of other risk factors, retinopathy is less likely to progress. With modern therapy, diabetic retinopathy is no longer the leading cause of sight loss in many parts of the developed world.

DIABETIC NEPHROPATHY

Diabetic nephropathy, which is the most common single cause of end-stage renal failure in Western societies, is discussed in Chapter 109.

DIABETIC NEUROPATHY

Diabetic neuropathy, which has an estimated lifetime prevalence of about 50% in individuals with diabetes, can cause a distal symmetrical polyneuropathy, autonomic neuropathy, and radiculoplexopathy. Diabetic neuropathy is discussed in Chapter 388.

DIABETIC FOOT

The combination of sensory impairment, due to peripheral sensory and autonomic neuropathy, and reduced tissue perfusion, due to large-vessel atherosclerosis (peripheral arterial disease) or microvascular dysfunction, can result in ulceration, infection, and ultimately lower extremity amputation (Chapter 65). Ulceration, often surrounded by callus formation, typically develops on the plantar surface of the foot, often underneath the metatarsal heads. Ulceration can be slow to heal because of repetitive trauma, impaired blood flow, and hyperglycemia. In the absence of protective sensation, an infection may fester for weeks and eventually invade the bone, thereby leading to osteomyelitis (Chapter 251). Altered foot mechanics can also lead to repeated (and usually undetected) fractures that destroy normal foot architecture and result in the classic Charcot foot deformity.

TREATMENT

Ulcers are treated with aggressive débridement of necrotic tissue and systemic antibiotics (guided by culture of infected tissue) if infection is present.[35] Pressure "off-loading" by use of special shoes, orthotics, or application of total-contact casts may be necessary to allow healing. Revascularization is required in patients who have significant peripheral arterial disease. Additional treatments such as specific dressings with healing accelerators and the use of autologous leukocytes and platelets may benefit patients who have nonhealing ulcers. Other treatments, including bioengineered skin substitutes, hyperbaric oxygen, and negative-pressure wound therapy have been tried but have not been proven to promote wound healing.

PREVENTION

Routine foot examination, especially for those who have evidence of sensory loss, should be performed at every medical visit, and individuals should be instructed to inspect their feet daily for cracks, fissures, ulcers, or inflammation. People with diabetes should avoid walking barefoot (even at home) and should wear protective covering (avoid sandals) outside. Thermal injuries can be prevented by avoiding use of heating pads or hot-water bottles on the feet. Referral to a foot care specialist should be considered for patients with sensory loss, foot deformity, extensive callus formation, and nonhealing ulcers.

DIABETIC CARDIOVASCULAR DISEASE

Macrovascular diabetic complications, specifically atherosclerotic cardiovascular disease, is the major cause of morbidity and mortality in patients with diabetes.

PATHOBIOLOGY

Metabolic factors, including hyperglycemia, insulin resistance, dyslipidemia, and increases in circulating free fatty acids, contribute to the formation of atherosclerotic plaques (Chapter 41). Increases in oxidation and glycoxidation of lipoproteins increase their atherogenicity and enhance the formation of foam cells. Endothelial dysfunction and inflammation also promote atherosclerosis and a prothrombotic state.

CLINICAL MANIFESTATION AND DIAGNOSIS

The clinical and pathologic features of cardiovascular disease in diabetes are generally not distinguishable from those occurring in nondiabetic individuals, but they are manifested at an earlier age, are more aggressive, and are associated with mortality rates that are two to four times higher in patients with diabetes (Chapter 40). Manifestations include coronary (Chapters 56-58), cerebral (Chapters 376 and 377), and peripheral arterial disease (Chapter 66), as well as an increased risk for diseases of the aorta (Chapter 63). Diabetes can also cause a cardiomyopathy (Chapter 47) with alterations in cardiac structure and function that are not directly attributable to coronary artery disease or hypertension. Characteristic features include cardiac hypertrophy, left ventricular dysfunction (diastolic may precede systolic), and altered myocardial metabolism.

The cardiovascular evaluation of an individual with diabetes is the same as for nondiabetic individuals. However, the threshold for diagnostic testing should be lower because of the increased prevalence of cardiovascular disease.

TREATMENT

Treatment of the acute atherosclerotic complications of diabetes is generally identical to the treatment in nondiabetic patients. However, people with diabetes and multivessel coronary disease have a better outcome (reduced rates of death from any cause or nonfatal myocardial infarction) with coronary artery bypass surgery compared with percutaneous intervention with drug-eluting stents (Chapter 59).[A37,A38]

PREVENTION

Aggressive control of cardiovascular disease risk factors, and especially of glucose levels, lipid levels, and blood pressure, is key.[36]

Glucose

Every 1% rise in the HbA_{1c} level is associated with a 40% increase in cardiovascular mortality, and intensive glucose control reduces cardiovascular events by about 60% in patients with type 1 diabetes. In type 2 diabetes, large trials have failed to show that aggressive control of hyperglycemia reduces atherosclerotic cardiovascular events, but SGLT-2 inhibitors and some glucagon-like peptide agonists can substantially reduce future cardiovascular events and all-cause mortality independently of their specific glycemic effects (see Treatment of type 2 diabetes).[A39]

Hypertension

Hypertension (Chapter 64), which is a common comorbid condition in diabetes, increases the risk of microvascular and macrovascular complications. The blood pressure goal should be less than 130/80 mm Hg for most people with diabetes. ACE inhibitors and angiotensin receptor blockers are generally considered first-line therapy for patients with diabetes (Chapter 64), but β-blockers, calcium-channel blockers, and low-dose diuretics are also recommended as add-on therapy if needed to achieve blood pressure targets. However, β-blockers should be used with caution in patients at high risk for hypoglycemia because they may blunt the autonomic warning symptoms associated with low glucose concentration.

Dyslipidemia

The characteristic atherogenic dyslipidemia of type 2 diabetes and insulin-resistant states includes low levels of high-density lipoprotein (HDL) cholesterol, elevated triglyceride levels, and elevated levels of small dense low-density lipoprotein (LDL) particles (Chapter 190). Lowering LDL cholesterol levels with statin drugs is recommended to a target of less than 100 mg/dL (2.6 mmol/L) for most adults with diabetes and less than 70 mg/dL (1.8 mmol/L) for people with diabetes with established cardiovascular disease or multiple risk factors, regardless of the baseline LDL cholesterol levels. People with diabetes with established atherosclerotic cardiovascular disease or an estimated 10-year cardiovascular risk of more than 7.5% should receive high-intensity statin treatment (regimens sufficient to lower LDL cholesterol >50% from untreated baseline), whereas all others would be considered for moderate-intensity treatment (lowering of LDL cholesterol 30 to <50%) (Table 190-2). Statin therapy slightly increases hyperglycemia, but the risk is small in magnitude (hazard ratio, about 1.2-fold increased risk of diabetes) and is far outweighed by the substantial benefits of cardiovascular protection. Specific therapy to lower triglyceride levels usually is not warranted (Chapter 190).

Antiplatelet Therapy

In people with diabetes, aspirin is not effective for the primary prevention of cardiovascular disease and increases bleeding events.[A40] Current guidelines recommend aspirin therapy 75 to 81 mg daily as secondary prevention for people who have diabetes and who have had a prior cardiovascular event. For high-risk individuals who are unable to tolerate aspirin, clopidogrel (75 mg orally once daily) is an effective alternative.

PROGNOSIS

The prognosis of cardiovascular disease in individuals with diabetes is qualitatively similar to nondiabetic individuals but tends to be worse for all clinical manifestations.

211 HYPOGLYCEMIA

KHALID HUSSAIN

DEFINITION

Hypoglycemia is a common biochemical abnormality observed in clinical practice. Hypoglycemic disorders are more frequent in neonates, infants, and children than adults. Delay in diagnosis and inappropriately treated hypoglycemia can have severe consequences, including seizures, permanent brain injury, or death.[1]

In adults, no single plasma glucose concentration categorically defines hypoglycemia. Rather, clinical hypoglycemia is defined as a plasma (or serum) glucose concentration low enough to cause symptoms or signs, which can be nonspecific but include impairment of brain function. The measured plasma or serum glucose concentration may be low owing to an artifact (e.g., when the blood sample is collected in a tube that does not contain an inhibitor of glycolysis and when separation of the plasma or serum from the formed elements is delayed).

For these reasons, guidelines in adults emphasize the value of the Whipple triad for confirming hypoglycemia: (1) symptoms and/or signs compatible with hypoglycemia, (2) a low measured plasma glucose concentration, and (3) resolution of symptoms and signs when glucose concentrations are raised. Because circulating fuels such as ketone bodies can be used by the brain, lower plasma glucose concentrations can occur in healthy individuals, particularly in women and children, without symptoms or signs during extended fasting.

EPIDEMIOLOGY

Hypoglycemic disorders in neonates, infants, and children are most often due to congenital or genetic disorders, such as disorders of insulin secretion, as well as a range of metabolic and endocrine diseases.[2] Early recognition and treatment of such persistent hypoglycemia disorders are critical to avoid developmental abnormalities, including permanent brain damage, which occurs in about 50% of cases with congenital hyperinsulinism.[3]

In adults, the overwhelming cause of hypoglycemia is as an adverse effect of anti-diabetes medicines, especially insulin. Other causes include hormone deficiencies, critical illness, and tumors that secrete insulin or insulin-like peptides (Table 211-1).

PATHOBIOLOGY

Plasma glucose concentration is regulated by a balance between glucose production and utilization. Glucose is derived from three sources: intestinal absorption after digestion of dietary carbohydrates; glycogenolysis (i.e., the breakdown of glycogen), which is the polymerized storage form of glucose; and gluconeogenesis, which is the formation of glucose from precursors (lactate, pyruvate, alanine, glutamine, and glycerol). Glucose is an obligate metabolic fuel for the brain, which cannot oxidize fatty acids or synthesize or store glucose for later use. To meet these needs, the rate of endogenous glucose influx into the circulation and glucose efflux out of the circulation (Fig. 211-1) into insulin-dependent tissues (skeletal muscle, adipose tissue, and liver) is regulated so that the plasma glucose concentration is maintained in a relatively narrow range between 70 and 110 mg/dL (3.8 to 6 mmol/L) despite periods of feeding and fasting.

211 HYPOGLYCEMIA

KHALID HUSSAIN

DEFINITION

Hypoglycemia is a common biochemical abnormality observed in clinical practice. Hypoglycemic disorders are more frequent in neonates, infants, and children than adults. Delay in diagnosis and inappropriately treated hypoglycemia can have severe consequences, including seizures, permanent brain injury, or death.[1]

In adults, no single plasma glucose concentration categorically defines hypoglycemia. Rather, clinical hypoglycemia is defined as a plasma (or serum) glucose concentration low enough to cause symptoms or signs, which can be nonspecific but include impairment of brain function. The measured plasma or serum glucose concentration may be low owing to an artifact (e.g., when the blood sample is collected in a tube that does not contain an inhibitor of glycolysis and when separation of the plasma or serum from the formed elements is delayed).

For these reasons, guidelines in adults emphasize the value of the Whipple triad for confirming hypoglycemia: (1) symptoms and/or signs compatible with hypoglycemia, (2) a low measured plasma glucose concentration, and (3) resolution of symptoms and signs when glucose concentrations are raised. Because circulating fuels such as ketone bodies can be used by the brain, lower plasma glucose concentrations can occur in healthy individuals, particularly in women and children, without symptoms or signs during extended fasting.

EPIDEMIOLOGY

Hypoglycemic disorders in neonates, infants, and children are most often due to congenital or genetic disorders, such as disorders of insulin secretion, as well as a range of metabolic and endocrine diseases.[2] Early recognition and treatment of such persistent hypoglycemia disorders are critical to avoid developmental abnormalities, including permanent brain damage, which occurs in about 50% of cases with congenital hyperinsulinism.[3]

In adults, the overwhelming cause of hypoglycemia is as an adverse effect of anti-diabetes medicines, especially insulin. Other causes include hormone deficiencies, critical illness, and tumors that secrete insulin or insulin-like peptides (Table 211-1).

PATHOBIOLOGY

Plasma glucose concentration is regulated by a balance between glucose production and utilization. Glucose is derived from three sources: intestinal absorption after digestion of dietary carbohydrates; glycogenolysis (i.e., the breakdown of glycogen), which is the polymerized storage form of glucose; and gluconeogenesis, which is the formation of glucose from precursors (lactate, pyruvate, alanine, glutamine, and glycerol). Glucose is an obligate metabolic fuel for the brain, which cannot oxidize fatty acids or synthesize or store glucose for later use. To meet these needs, the rate of endogenous glucose influx into the circulation and glucose efflux out of the circulation (Fig. 211-1) into insulin-dependent tissues (skeletal muscle, adipose tissue, and liver) is regulated so that the plasma glucose concentration is maintained in a relatively narrow range between 70 and 110 mg/dL (3.8 to 6 mmol/L) despite periods of feeding and fasting.

ABSTRACT

Hypoglycemia is one of the most common biochemical abnormalities observed in clinical practice. Hypoglycemic disorders are more common in neonates, infants, and children than in adults. Delay in diagnosis and inappropriate management of hypoglycemia can have severe consequences, including seizures, permanent brain injury, or death. In adults, an insulinoma is the most common cause of endogenous hyperinsulinemic hypoglycemia, and other causes of hypoglycemia are relatively rare. This chapter outlines the physiologic and biochemical changes associated with maintenance of a normal blood glucose level, describes the role of the counter-regulatory hormones, reviews the clinical manifestations and diagnosis of hypoglycemic disorders, and discusses management strategies.

TABLE 211-1 DIFFERENTIAL DIAGNOSIS OF HYPOGLYCEMIA*

HYPERINSULINEMIC HYPOGLYCEMIA (INCLUDING POSTPRANDIAL)
Transient: infant of diabetic mother, perinatal asphyxia, Rhesus disease, intrauterine growth restriction, Beckwith-Wiedemann syndrome
Congenital: *ABCC8, KCNJ11, GCK, GDH, HADH, HNF4A, HNF1A, SLC16A1, UCP2, HK-1, PGM-1, PMM2, FOXA2, CACNA1D*
Dumping syndrome
Insulin receptor mutations and antibodies
Hypoketotic hypoinsulinemic hypoglycemia with overgrowth
Activating mutations in *AKT2, AKT3, CCND2, PIK3R2,* and *PIK3CA*
Insulinoma
Non-insulinoma pancreatogenous hypoglycemia (adults)
Gastric bypass surgery for morbid obesity
Non–islet cell tumor hypoglycemia or IGF-2-oma
Insulin autoimmune syndrome
Insulin factitious hypoglycemia
HORMONAL DEFICIENCY/RESISTANCE
Adrenocorticotropic hormone
Cortisol
Growth hormone
Glucagon†
Adrenaline†
DRUG-INDUCED
Oral hypoglycemic agents
Insulin
β-Blockers
Salicylates
Alcohol
Quinine
Haloperidol
Pentamidine
Levofloxacin
Methadone
Disopyramide
Indomethacin
Cibenzoline
Gatifloxacin
DEFECTS IN HEPATIC GLYCOGEN RELEASE/STORAGE
Glycogen storage diseases: **glucose-6-phosphatase deficiency**, **amylo-1,6-glucosidase deficiency**, liver phosphorylase deficiency, glycogen storage disease type 0
DEFECTS IN GLUCONEOGENESIS
Fructose-1,6-bisphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency, pyruvate carboxylase deficiency
CARNITINE METABOLISM
Carnitine deficiency (primary and secondary)
Carnitine palmitoyltransferase deficiency (CPT 1 and 2)
Carnitine transporter defects
FATTY ACID OXIDATION
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency
Very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency
Short-chain acyl-CoA dehydrogenase (SCAD) deficiency
Long/short-chain L-3-hydroxyacyl-CoA (L/SCHAD) deficiency
DEFECTS IN KETONE BODY SYNTHESIS/UTILIZATION
HMG-CoA synthase deficiency, HMG-CoA lyase deficiency
Succinyl-CoA: 3-oxoacid-CoA transferase (SCOT) deficiency
METABOLIC CONDITIONS (COMMON ONES)
Organic acidemias (propionic, methylmalonic)
Maple syrup urine disease, galactosemia, fructosemia, tyrosinemia
Hereditary fructose intolerance
Mitochondrial respiratory chain complex deficiencies
Congenital disorders of glycosylation (CDG)
Citrin deficiency
TOXIN-INDUCED
Lychee fruit
MISCELLANEOUS CAUSES (MECHANISM[S] NOT CLEAR)
Idiopathic ketotic hypoglycemia (diagnosis of exclusion)
Infections (sepsis, malaria), congenital heart disease

*Boldface indicates more common in adults.
†No human case yet reported with glucagon or adrenaline deficiency.
HMG = 3-hydroxy-3-methylglutaryl; IGF = insulin-like growth factor.

Changes During Fasting

During fasting, the basal rate of glucose output by the liver (2.2 mg/kg/minute in healthy adults after an overnight fast) is precisely matched to glucose uptake by various body tissues. The brain is responsible for nearly two thirds of basal glucose utilization, with the remaining one third used by red blood cells, the renal medulla, and, to some extent, muscle and fat.

Glucose production results largely from a combination of glycogenolysis and gluconeogenesis in the liver, with some contribution from renal gluconeogenesis. Breakdown of stored hepatic glycogen is a readily available source of free glucose. In an average adult, however, glycogenolysis can provide less than an 8-hour supply of free glucose, so gluconeogenesis is important to augment hepatic glycogen stores during an overnight fast.

The key enzymes involved in gluconeogenesis are pyruvate carboxylase, phosphoenolpyruvate carboxykinase, and fructose-1,6-bisphosphatase. Muscle and adipose tissue, which utilize glucose in the fed state, respond to prolonged fasting by reducing their glucose uptake and satisfying their energy requirements by the β-oxidation of fatty acids. Additionally, through the process of proteolysis, muscle tissue provides amino acids to the liver to serve as gluconeogenic precursors for net glucose formation. Changes in the hormonal milieu during fasting (suppressed insulin and elevated counter-regulatory hormones) stimulate the formation of ketones, which serve as a substitute fuel and diminish the need to catabolize protein as a source of gluconeogenesis.

Changes During Feeding

After a meal, plasma glucose concentrations increase, stimulate the secretion of insulin from the pancreatic β-cells, and suppress secretion of glucagon from the pancreatic α-cells. This change in the hormonal milieu switches off endogenous hepatic glucose production and accelerates glucose utilization by liver, muscle, and adipose tissue. The glucose concentration then returns gradually to the post-absorptive level, at which the endogenous production of glucose is equal to the uptake of glucose by peripheral tissues.

Counter-Regulatory Hormonal Responses to Hypoglycemia

Counter-regulatory hormones play a key role in the maintenance of a normal plasma glucose concentration (Fig. 211-2).[4] Neurons in the portal and mesenteric veins detect changes in blood glucose prior to entry into the liver from the gut. This information is then relayed through the vagus nerve and spinal cord to the hindbrain and then to the hypothalamus. In addition, the hypothalamus, because of its location adjacent to the third ventricle and median eminence, may sample factors from peripheral circulation, including glucose, as well as hormones such as insulin and leptin. Ventromedial neurons in the hypothalamus contain the same glucose-sensing mechanisms (e.g., glucokinase, adenosine triphosphate [ATP]-sensitive K^+ channels) as found in pancreatic β-cells. In healthy individuals, this counter-regulatory system ensures that hypoglycemia is rarely experienced and would occur only during starvation or ultra-endurance sports. During the counter-regulatory hormonal response, a reduction in the plasma glucose concentration will result in a decrease in the secretion of insulin and an increase in the secretion of glucagon, epinephrine, norepinephrine, cortisol, and growth hormone secretion. Any drug or disease that inhibits the counter-regulatory system can predispose the patient to hypoglycemia.

The secretion of glucagon increases rapidly in response to decreasing plasma glucose levels, and this glucagon response is the primary essential defense mechanism against acute hypoglycemia. Insulin secretion from pancreatic β-cells is reduced in healthy individuals when the plasma glucose concentration falls below 72 mg/dL (4.0 mmol/L). As insulin secretion is reduced, the repressive effect of insulin on pancreatic α-cell function is removed, thereby rapidly increasing glucagon secretion. Glucagon acts on the liver to increase hepatic glycogenolysis and gluconeogenesis. When the plasma glucose concentration falls below about (68 mg/dL [3.8 mmol/L]), epinephrine and norepinephrine are released from the adrenal glands and nerve terminals, thereby further suppressing insulin secretion, increasing glucagon secretion, and decreasing peripheral glucose utilization in the muscle and increasing lipolysis in the adipose tissues.

Growth hormone and cortisol increase the rate of gluconeogenesis and antagonize the effects of insulin. In adults, the secretion of cortisol and growth hormone increases in response to plasma glucose concentrations within the normoglycemic range. Additional secretion of growth hormone and cortisol occurs below a plasma glucose concentration of about 66 mg/dL (3.7 mmol/L), and these hormones initiate the adaptive response to hypoglycemia (e.g., during prolonged starvation); glucose-raising actions are much slower in onset (several

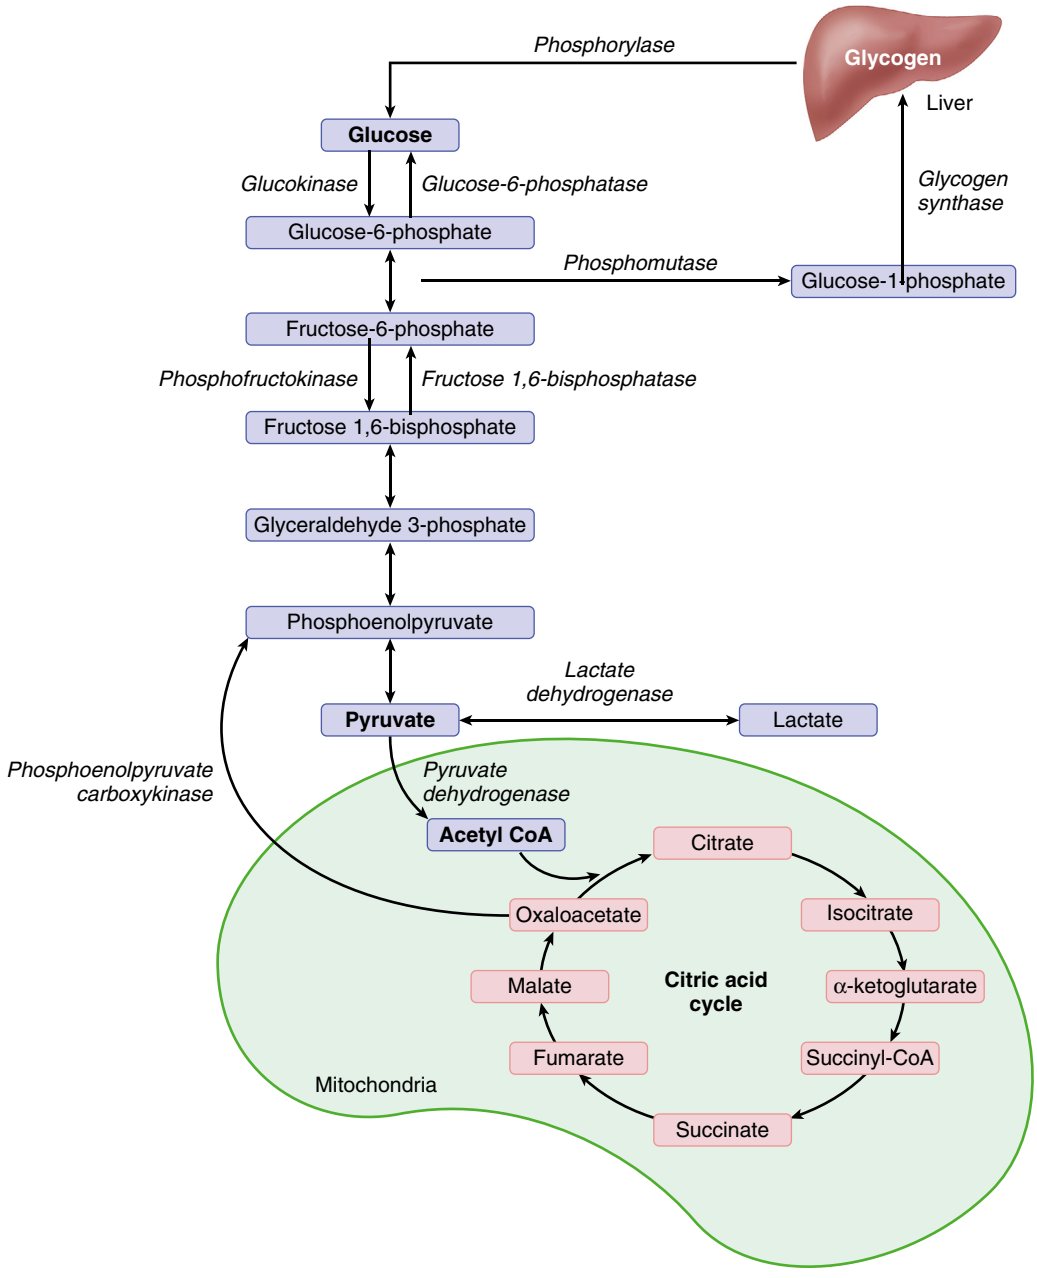

FIGURE 211-1. Outline of the biochemical pathways involved in the physiology of glucose.

hours). These hormone responses stimulate lipolysis, ketogenesis, and gluconeogenesis. Permissive amounts of cortisol and growth hormone are required for a normal hepatic response to glucagon and epinephrine.

CLINICAL MANIFESTATIONS

Symptoms of Hypoglycemia

The symptoms of hypoglycemia, which reflect the responses of the brain to a decrease in the blood glucose level, can be nonspecific and vague. Some symptoms arise as a result of the central nervous system being deprived of glucose (neuroglycopenic), whereas others arise from physiologic changes caused by the central nervous system–mediated, sympatho-adrenal discharge that is triggered by the hypoglycemia (neurogenic or autonomic). The neurogenic symptoms of hypoglycemia are largely the result of sympathetic neural, rather than adrenomedullary, activation.

Neuroglycopenic symptoms (e.g., dizziness, confusion, tiredness, difficulty with speaking, headache, inability to concentrate, coma, and seizures) arise from the failure of brain function itself and are caused by deficient supply of glucose. Neurogenic symptoms include both adrenergic responses (catecholamine-mediated symptoms, such as palpitations, tremor, and anxiety) and cholinergic responses (acetylcholine-mediated symptoms, such as sweating, hunger, paresthesias). Awareness of hypoglycemia chiefly depends on perception of the central and peripheral effects of neurogenic (as opposed to neuroglycopenic) responses.

In nondiabetic adults during acute insulin-induced hypoglycemia, autonomic symptoms become apparent at a threshold of approximately 60 mg/dL (3.3 mmol/L), whereas impairment of brain function manifested by neuroglycopenic symptoms occurs at a threshold of approximately 50 mg/dL (2.8 mmol/L) in arterialized venous blood (venous levels would be ≈3 mg/dL [0.16 mmol/L] less). However, the glycemic thresholds for responses to hypoglycemia are reset at a lower plasma glucose concentration in patients with recurrent hypoglycemia. In nondiabetic individuals, the symptoms and signs of hypoglycemia are not influenced by the rate of the decline in blood glucose levels.

SPECIFIC CAUSES OF HYPOGLYCEMIA

Hypoglycemia is more common in childhood than in adulthood, and the cause can also vary by age (see Table 211-1).

Critical Illness

Hypoglycemia frequently occurs in patients in the critical care setting and is associated with factors such as sepsis, multiorgan failure, and the inappropriate use of intensive insulin therapy. The successful management of blood glucose levels during critical illness is associated with improved outcomes.

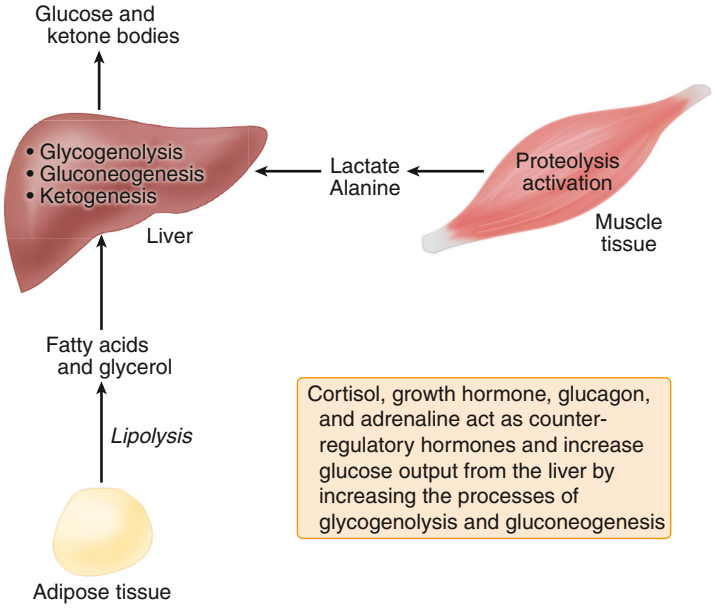

FIGURE 211-2. **The role of the counter-regulatory hormones, glycogenolysis, gluconeogenesis, and lipolysis in glucose physiology.**

Excess Production of Hormones

The two most common conditions associated with excess production are hyperinsulinemic hypoglycemia and non–islet cell tumors that secrete insulin-like growth factor (IGF).[5] The inappropriate production of insulin can lead to either fasting or postprandial hypoglycemia.

Hyperinsulinemic hypoglycemia is caused by a heterogeneous group of disorders characterized by unregulated insulin secretion from pancreatic β cells. When hypoglycemic patients have inappropriately detectable serum insulin (or C-peptide) levels, low ketone bodies, and low fatty acids, they have a glycemic response to glucagon.

Congenital Hyperinsulinemia

Congenital hyperinsulinemic hypoglycemia is related to mutations in the key genes (*ABCC8, KCNJ11, GLUD1, GCK, HADH, SLC16A1, HNF4A, HNF1A, HK-1, PGM-1, UCP2, PMM2, FOXA2,* and *CACNA1D*) that regulate insulin secretion.[6] Hyperinsulinism–hyperammonemia syndrome owing to activating mutations in the *GLUD1* gene or activating mutations in the *GCK* gene have also been described in adults, as has exercise-induced hyperinsulinemic hypoglycemia owing to activating mutations in the *SLC16A1* gene. Activating mutations in the *AKT2, AKT3, PIK3CA, PIK3R2,* and *CCND2* genes lead to autonomous activation of the insulin signaling pathway but no detectable insulin in the blood.[7]

Insulin-Receptor Mutations

Postprandial hyperinsulinemic hypoglycemia can be caused by a heterozygous mutation (Arg1174Gln) in the insulin-receptor gene. Hyperinsulinism is associated with decreased degradation rather than increased secretion of insulin, despite normal levels of serum C-peptide and reduced clearance of exogenous insulin during clamp studies.

Insulinoma

The most common cause of endogenous hyperinsulinemic hypoglycemia in adults is an insulinoma,[8] which is an insulin-secreting tumor of pancreatic origin, with an incidence of 1 to 4 cases per million, peaking in the fifth and sixth decades. The majority (90%) are benign, solitary, intrapancreatic, and less than 2 cm in diameter, but 5 to 10% are malignant.[9] Symptoms classically become evident in the fasting state or following exercise, but insulinomas also can present with postprandial symptoms. An insulinoma can occur either in isolation or in association with multiple endocrine neoplasia type 1 (MEN 1), with a lifetime prevalence of 10% among adults carrying mutations in *MEN1* (Chapter 212). About 6% of insulinomas occur in patients with MEN 1. Recurrent somatic mutations in the *YY1* gene occur in some sporadic insulinomas, and some insulinomas show increased expression of hexokinase-1.

Postprandial Hyperinsulinemic Hypoglycemia

Postprandial hyperinsulinemic hypoglycemia refers to hypoglycemia within a few hours after a meal because of inappropriate secretion of insulin in response to it. When postprandial hyperinsulinemic hypoglycemia is clinically suspected, an oral glucose tolerance test or a mixed-meal provocation test is recommended. A physiologic dip in the blood glucose level seen in the oral glucose tolerance test might lead to misdiagnosis. However, corresponding biochemical evidence of endogenous hyperinsulinemic hypoglycemia and symptoms of neuroglycopenia during a hypoglycemic episode help distinguish between pathologic postprandial hyperinsulinemic hypoglycemia and reactive hypoglycemia.

Dumping Syndrome

In adults, dumping syndrome can be seen after esophageal (distal esophagectomy, myotomy for achalasia), gastric (Nissan wrap, hiatal hernia repair, gastrojejunostomy), and bariatric (Roux-en-Y and duodenal switch gastric bypass) surgeries (Chapter 201). The rapid delivery of food, including sugars, into the duodenum and jejunum alters the regulation of insulin and can lead to postprandial hyperinsulinemic hypoglycemia.[10]

The hypoglycemia may be due to an effect on the enteroinsular axis induced by the diversion of nutrients into the small intestine. The enhanced postprandial insulin secretion involves increased secretion of glucagon-like peptide 1 (GLP-1), and glucose-dependent insulinotropic polypeptide (GIP) GLP-1 levels are increased two- to five-fold after gastric bypass. IGF-2 and IGF-1 receptor alpha (IGF1Rα) also are overexpressed. A decrease of more than 108 mg/dL (6 mmol/L) between peak and nadir blood glucose levels during an oral glucose tolerance test has been used as a diagnostic criterion for dumping syndrome in adults.

Insulin Autoimmune Syndrome

Insulin autoimmune syndrome (Hirata disease) is a rare condition characterized by hyperinsulinemic hypoglycemia caused by physiologically inappropriate levels of bioavailable insulin associated with high titers of antibodies to endogenous insulin in the absence of prior exposure to exogenous insulin.[11] It affects men and women equally and is seen more frequently in patients older than age 40 years.

After a meal or glucose load, these patients often demonstrate initial hyperglycemia, followed by hypoglycemia a few hours later. The hyperglycemia is caused by the anti-insulin antibodies that bind the insulin secreted in response to rising blood glucose levels after a meal. This binding reduces the bioavailability of the secreted insulin to the receptors in the liver and peripheral tissues, thereby resulting in hyperglycemia and further insulin secretion. Insulin levels are markedly elevated, usually above 100 mU/L. As blood glucose concentrations begin to decrease and insulin secretion declines, the insulin bound to the antibodies is released, thereby resulting in inappropriately high free insulin concentrations for the blood glucose, causing hypoglycemia.

Non-Insulinoma Pancreatogenous Hypoglycemia Syndrome

Non-insulinoma pancreatogenous hypoglycemia syndrome is characterized by postprandial neuroglycopenia despite negative prolonged fasting tests and negative perioperative localization studies for insulinoma. Immunohistologic studies of resected pancreatic tissue do not show an increased rate of proliferation of β-cells or abnormal synthesis or processing of either proinsulin or amylin, and the cause is unknown. In some patients, however, the selective arterial calcium stimulation test is positive, with the histology of the resected pancreas showing nesidioblastosis. Otherwise, the cause of this syndrome is unknown.

Insulin Factitious Hypoglycemia

Hypoglycemia also can be induced pharmacologically, either intentionally as a diagnostic tool, accidentally as a complication of the treatment of diabetes mellitus (Chapter 210), or as a consequence of poisoning either with insulin itself or with oral or subcutaneous hypoglycemia drugs that stimulate insulin release. Whenever severe hypoglycemia occurs with documented hyperinsulinism, the possibility of Munchausen syndrome or Munchausen syndrome by proxy should be considered. The possibility of malicious administration of insulin or other hypoglycemia drugs should always be suspected in cases of sudden onset of hypoglycemia in a previously healthy individual. In cases of insulin administration, laboratory testing will show a raised insulin level accompanied by a normal C-peptide level.

Tumor-Associated Hypoglycemia

Non–islet cell tumor hypoglycemia denotes the syndrome of hypoglycemia produced by or associated with any neoplasm other than an insulinoma (Chapter 164).[12] These tumors are usually of mesenchymal or epithelial origin (including hepatomas, fibromas, and fibrosarcomas). The underlying mechanism of hypoglycemia in nearly all patients with this syndrome is overproduction by the tumor of insulin growth factor-2, which includes mature insulin growth factor-2 and incompletely processed forms of insulin growth factor-2, referred to collectively as "big" insulin growth factor-2. The elevated insulin growth factor-2–related peptides mimic the fasting hypoglycemia that is characteristic of patients with insulin-producing islet cell tumors. Rarely, markedly elevated insulin growth factor-2 levels produce somatic changes suggestive of acromegaly. Typically, the elevated insulin growth factor-2 levels are associated with suppressed plasma levels of insulin, insulin growth factor-1, and growth hormone. Hypoglycemia can also occur due to paraneoplastic secretion of insulin-like growth factor-1.

Drug- and Toxin-Induced Hypoglycemia

A number of drugs have been linked to hypoglycemia (see Table 211-1). Mechanisms vary, and, except for insulin and oral hypoglycemic agents, the risks in any individual are very low.

The white-fleshed lychee berry has been implicated as the cause of large-scale, severe hypoglycemia in the Bihar state of India. In some cases, however, the clinical history and physical examination may not provide any clues, and these patients will need more extensive investigation.

In an ideal situation, the blood glucose level should be measured at the time of a spontaneous episode of hypoglycemia. In addition, levels of insulin, C-peptide, proinsulin, and β-hydroxybutyrate should be measured and a toxicology screen for oral hypoglycemic agents should be performed. If the diagnosis is not obvious, additional laboratory testing (Table 211-2) may be helpful. However, provocative testing is often required.

Hypoglycemia Due to Hormone Deficiency

Deficiencies in growth hormone, adrenocorticotropic hormone (ACTH), or cortisol, alone or in combination with other hormones, can lead to hypoglycemia by reducing the mobilization of fats and proteins, as well as by increasing the utilization of glucose owing to increased insulin sensitivity of tissues in the absence of these two hormones. Acquired hypopituitarism (Chapter 205) may result from tumors (most commonly craniopharyngioma), radiation, infection, hydrocephalus, vascular anomalies, and trauma. Addison disease (Chapter 208) results from adrenal cortical hypofunction/dysfunction, with deficient production of glucocorticoids, mineralocorticoids, and androgens, associated with high levels of both ACTH and plasma renin activity (Chapter 208). Autoimmune Addison disease accounts for about 80% of cases in adults, with 10 to 15% of cases caused by tuberculosis infection (Chapter 299) and the remaining 5% by vascular, neoplastic, or rare genetic forms.

Hypoglycemia Due to Defects in Hepatic Glycogen Release/Storage

Homozygous glucose-6-phosphatase deficiency (glycogen storage disease type I, Von Gierke disease) is the most common glycogen storage disease that causes hypoglycemia (Chapter 191). Deficiency of this enzyme results in the inability to release free glucose from glucose-6-phosphate, with resultant hepatomegaly due to stored glycogen. These children and adults present with recurrent hypoglycemia associated with lactic acidosis, hyperuricemia, and hyperlipidemia. The two other glycogen storage diseases causing hypoglycemia are due to deficiencies of the enzymes amylo-1,6-glucosidase (glycogen storage disease type III) and liver phosphorylase (glycogen storage disease type VI). (See Chapter 191.)

Hypoglycemia Due to Defects in Gluconeogenesis

Gluconeogenesis, or the formation of glucose from mainly lactate/pyruvate, glycerol, glutamine, and alanine, plays an essential role in the maintenance of normoglycemia during fasting. Inborn deficiencies are known in each of the four enzymes of the glycolytic-gluconeogenic pathway: pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Patients with defects in gluconeogenesis present with fasting hypoglycemia and lactic acidosis.

Disorders of Carnitine Metabolism and Fatty Acid Oxidation

Disorders of fatty acid oxidation are individually rare but are collectively more common because of the number of different enzymes affected. Fatty acids are taken up by hepatocytes and muscle, where they are subsequently activated to their coenzyme A (CoA) esters. When fatty acid oxidation is impaired, clinical manifestations include hypoglycemic seizures, muscle damage, cardiomyopathy, metabolic acidosis, and liver dysfunction. When defects occur in fatty acid degradation, excess acylcarnitine intermediates accumulate in the heart, liver, and skeletal muscle, where it can lead to organ dysfunction. Acyl-carnitines that spill into the blood provide a marker for diagnosis.

Primary carnitine deficiency, which is an autosomal recessive disorder of fatty acid oxidation, can present at different ages with hypoketotic hypoglycemia, cardiomyopathy, or skeletal myopathy (Chapter 189). Patients with the hepatic isoform of carnitine palmitoyltransferase (CPT)-1 deficiency present with hypoketotic hypoglycemia in the neonatal period. This disease is suspected based on reduced levels of carnitine in plasma and confirmed by measurement of carnitine transport in the patient's fibroblasts.

The most common disorder of fatty acid β-oxidation is medium-chain acyl-CoA dehydrogenase deficiency,[13] which is an autosomal recessive disease that presents in children who are typically asymptomatic except during times of fasting or metabolic stress, when they present with fasting nonketotic hypoglycemia; if undiagnosed, 20 to 25% of affected patients will die during the first episode.

TABLE 211-2 ROUTINE BASELINE INVESTIGATIONS IN PATIENTS WITH SUSPECTED HYPOGLYCEMIA

BLOOD	URINE
Glucose	Ketones
Insulin	Reducing substances such as lactose and galactose
Cortisol	Propionic, methylmalonic, and isovaleric acids
Lactate	
Growth hormone	
Non-esterified fatty acids	
3β-Hydroxybutyrate	
Carnitine (free and total)	
Blood spot acylcarnitine	
Ammonia	

Metabolic Diseases

Hypoglycemia also can be due to a number of inherited metabolic conditions (Chapter 189), including galactosemia, fructosemia, tyrosinemia, organic acidemias, maple syrup urine disease, glutaric aciduria type II, defects in the mitochondrial respiratory chain, and citrin deficiency (see Chapter 189).

DIAGNOSIS

A careful clinical history, description of symptoms, physical examination, and a systematic approach is the cornerstone of establishing a diagnosis.[14] The symptoms of hypoglycemia may be very nonspecific, so a symptomatic patient must have the blood glucose level measured and documented.

Reagent strips in combination with a reflectance meter are the most common method of measuring bedside blood glucose levels. However, these tests can be inaccurate, so the blood glucose concentration should always be checked in the laboratory. Whole-blood glucose is approximately 15% lower than serum glucose levels because of the lower glucose content and intracellular water content of the red cells. Glucose concentrations in venous blood are 10% lower than arterial blood. The blood sample for glucose measurement should be collected in a fluoride container to inhibit glycolysis, and it also should be analyzed immediately because, even in the presence of fluoride, the blood glucose concentration will decrease over time.

The clinical history, description of symptoms, and physical examination may provide important clues to the underlying cause of hypoglycemia and guide the investigations. For example, hypoglycemia occurring after a short fast (2 to 3 hours) may be suggestive of hyperinsulinism or glycogen storage disease. Hypoglycemia occurring after a long fast (12 to 14 hours) may suggest a disorder of gluconeogenesis. Postprandial hypoglycemia may indicate dumping syndrome (including after gastric bypass surgery), insulinoma, insulin autoimmune syndrome, non-insulinoma pancreatogenous hypoglycemia syndrome, hereditary fructose intolerance, or galactosemia.

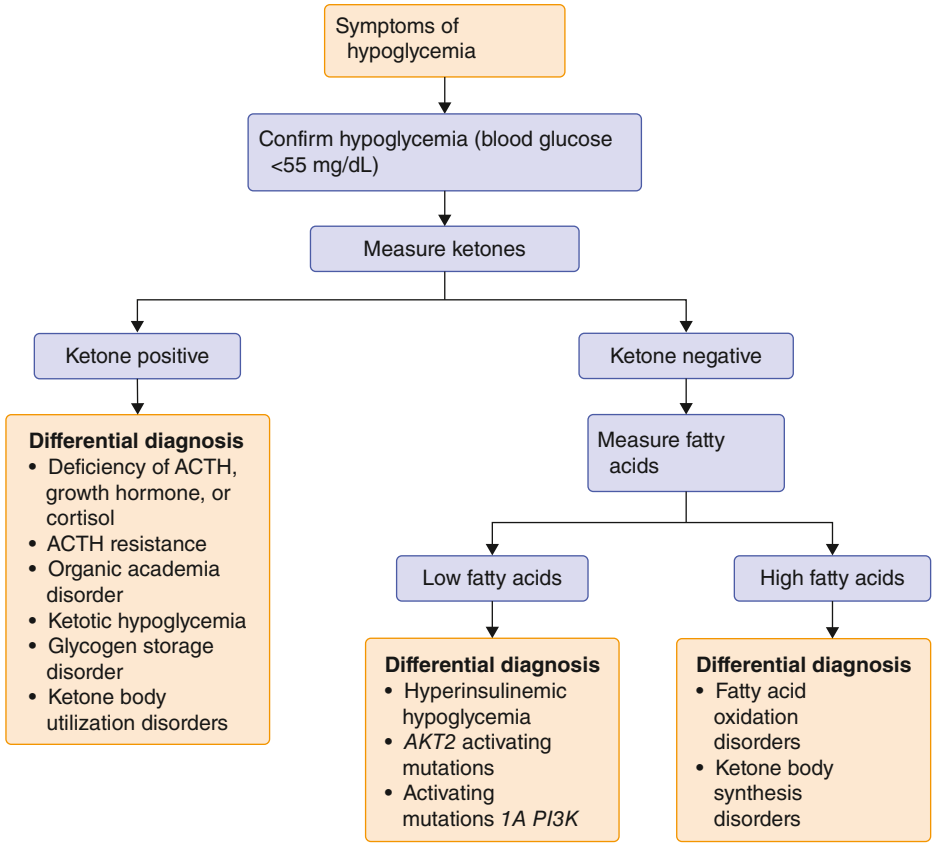

FIGURE 211-3. Diagnostic approach to hypoglycemia. ACTH = adrenocorticotropic hormone.

After the clinical history has been taken and the examination completed, a hypoglycemia diagnosis (see Table 211-1) should be a diagnostic cascade of appropriate tests that can evaluate the most common causes (Fig. 211-3). Because the signs and symptoms of hypoglycemia are nonspecific, this detailed evaluation should be undertaken only in patients who have the Whipple triad of symptoms, signs, or both consistent with hypoglycemia; a low plasma glucose concentration; and documented resolution of the symptoms or signs after the plasma glucose concentration is raised.

Fasting Tests

Controlled fasting tests are important procedures for eliciting the cause of hypoglycemia. In adults, the recommended approach is a prolonged (72-hour) supervised fast that is conducted in a standardized fashion (Table 211-3). The fast should be terminated if patients have any signs or symptoms of hypoglycemia accompanied by a documented plasma glucose concentration of 55 mg/dL (3 mmol/L) or less. The fast should not be prolonged beyond 72 hours if patients do not have any symptoms or signs of hypoglycemia or a documented low blood glucose level. Monitoring for symptoms or signs of hypoglycemia during the fast is essential because patients may experience symptoms but have serum glucose levels higher than the hypoglycemic range. In some healthy women (thin and lean) and men, blood glucose levels may drop to 40 mg/dL (2.2 mmol/L) during prolonged fasting. Some patients have lower glycemic thresholds without symptoms or signs of hypoglycemia.

The interpretation of serum insulin, C-peptide, and proinsulin during the 72-hour fast will depend on the concurrent plasma glucose concentration. Pancreatic β-cell insulin secretion becomes undetectable in healthy persons when the plasma glucose concentration falls to 55 mg/dL (3 mmol/L). Most patients with an insulinoma become hypoglycemic before 72 hours. However, continuation of the fast to 72 hours is necessary to exclude the likelihood of true hypoglycemia.

Hyperinsulinemic hypoglycemia in adults is characterized by plasma insulin concentrations of 3 μU/mL or greater (C-peptide of 200 pmol/L or more and proinsulin 5 pmol/L or more). Patients with insulinomas have plasma insulin concentrations that rarely exceed 100 μU/mL, and plasma insulin levels greater than 1000 μU/mL suggest exogenous insulin administration or the presence of insulin antibodies. In children, any detectable plasma insulin in the presence of hypoglycemia is inappropriate and is highly suggestive of hyperinsulinemic hypoglycemia.

Measurement of the plasma β-hydroxybutyrate concentration is used as a surrogate marker of insulin action at the end of the 72-hour fast in healthy adult individuals and when the Whipple triad is fulfilled during a diagnostic fast. In patients with hyperinsulinemic hypoglycemia, plasma concentrations of β-hydroxybutyrate are typically less than 2.7 mmol/L because of the suppressive action of insulin on ketogenesis. Healthy individuals will have a progressive rise in the concentration of β-hydroxybutyrate during the 72-hour test. If a value above 2.7 mmol/L is documented at any time point in the fast, the test can be terminated.

During the 72-hour prolonged fast, blood also should be collected for measurement of plasma sulfonylureas and meglitinides if the patient develops hypoglycemia. Sulfonylureas stimulate pancreatic secretion of β-cell insulin and C-peptide, and the biochemical pattern is similar to that of an insulinoma.

TABLE 211-3 PROTOCOL FOR 72-HOUR FAST IN ADULTS

1. Start the fast from the last ingestion of a meal. Stop all medications that might interfere with test.
2. The patient can drink water during the test.
3. The patient must be active during waking hours.
4. Measure plasma glucose, insulin, C-peptide, and β-hydroxybutyrate (on the same venipuncture specimen) every 6 hours until plasma glucose reaches 60 mg/dL (3.3 mM). Then measure every 1 to 2 hours.
5. End the fast when the plasma glucose is 45 mg/dL (2.5 mM) and the patient has symptoms or signs of hypoglycemia, or plasma glucose is 55 mg/dL if Whipple triad had been demonstrated previously.
6. At the end of the fast, measure plasma glucose, insulin, C-peptide, β-hydroxybutyrate, and sulfonylurea (on the same venipuncture specimen). Then inject glucagon, 1 mg intravenously, and measure plasma glucose every 10 minutes three times. Once the fast is completed, allow the patient to eat normally.

Adapted from Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2009;94:709-728.

TABLE 211-4 SUGGESTED PROTOCOL FOR A MIXED-MEAL DIAGNOSTIC TEST IN ADULTS

1. Fast patient overnight. Stop all medications that might interfere with test.
2. Use a mixed meal similar to one that causes patient to experience symptoms.
3. Collect samples for plasma glucose, insulin, C-peptide, and proinsulin before ingestion and every 30 minutes through 300 minutes after meal ingestion.
4. Observe the patient for symptoms and/or signs of hypoglycemia and ask the patient to keep a written log of all symptoms, timed from the start of meal ingestion.
5. The mixed-meal test should be interpreted on the basis of laboratory measured plasma glucose concentrations, not those estimated with a point-of-care glucose monitor. If it is judged necessary to treat before 300 minutes because of severe symptoms, obtain samples for all the following *before* administering carbohydrates: plasma insulin, C-peptide, and proinsulin (sent for analysis only in those samples in which plasma glucose is <60 mg/dL [3.3 mmol/L]), and a measurement of oral hypoglycemic agents. If Whipple's triad is demonstrated, antibodies to insulin should also be measured.

Adapted from Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2009;94:709-728.

Mixed-Meal Test

A mixed-meal test is performed in patients who have a history suggestive of neuroglycopenic symptoms for up to 5 hours after the ingestion of food (Table 211-4). A positive test is defined as the onset of neuroglycopenic symptoms in association with a documented low blood glucose level (e.g., ≤50 mg/dL). In postprandial hyperinsulinemic hypoglycemia, plasma insulin and C-peptide levels might be inappropriately elevated. Neuroglycopenic symptoms after a meal are reported in patients who have an insulinoma, patients who have the non-insulinoma pancreatogenous hypoglycemia syndrome, and patients who have undergone surgery for obesity.

The combination of a positive mixed-meal test and a negative 72-hour fast may occur in a patient with insulinoma or with non-insulinoma pancreatogenous hypoglycemia syndrome. The 5-hour oral glucose tolerance test should not be used as a sole diagnostic test for hypoglycemia, because a substantial percentage of healthy persons may have a serum glucose concentration of 50 mg/dL (2.7 mmol/L) or less.

Glucagon Stimulation

Another useful marker of insulin action is the glycemic increment in response to an intravenous/intramuscular injection of glucagon (1-mg dose in adults). Patients with hyperinsulinemic hypoglycemia will have increased glycogen stores, and glucagon will result in glycogenolysis. A positive response is defined as a maximal increment at least 25 mg/dL (1.3 mmol/L) greater than the terminal fasting serum glucose.

Insulin Antibodies

In patients with insulin autoimmune hypoglycemia, insulin antibodies, which may be monoclonal or polyclonal, are present in very high titers, in contrast to the much lower titers in insulin-treated diabetes. It is important to test for the presence of insulin antibodies, because even low titers—which may have no diagnostic significance—may cause spurious results of the assay for insulin. Hypoglycemia due to insulin autoimmune syndrome typically occurs in the fasting period but can occur postprandially as well.

Radiologic Investigations

When a diagnosis of insulinoma has been made, noninvasive imaging can often localize the source of pathologic insulin secretion. The sensitivity of transabdominal ultrasonography for the localization of insulinomas is poor (ranging from 9% to 64%). However, insulinomas demonstrate characteristic features when imaged with both computed tomographic (CT) scanning and magnetic resonance imaging (MRI), and the sensitivity of these techniques is 33 to 64% and 40 to 90%, respectively, with MRI generally superior to CT, especially for the detection of extra pancreatic extensions. Insulinomas generally demonstrate low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

Invasive modalities such as endoscopic ultrasound and arterial stimulation with venous sampling are highly accurate for the preoperative localization of insulinomas and are superior to noninvasive localization techniques. Endoscopic ultrasound is currently the test of choice in most Western centers, with reported detection rates of 86.6 to 92.3%. Arterial stimulation and venous sampling have greatly facilitated the precise regionalization of insulinomas smaller than 2 cm, which noninvasive techniques such as ultrasonography, CT, and MRI often fail to localize. A two- to three-fold increase in insulin concentration in the right hepatic vein in response to calcium injection into one or more of the arteries supplying the pancreas suggests that the region served by that artery may harbor abnormally functioning β-cells, whether from insulinoma or islet hypertrophy or nesidioblastosis. Calcium injection will stimulate a brisk response of insulin, C-peptide, and proinsulin simultaneously, and the magnitude of increase of both insulin and C-peptide appears to be correlated well with the degree of differentiation of the tumor cells. The positive responses to selective arterial calcium stimulation in some patients with non-insulinoma pancreatogenous hypoglycemia syndrome, despite negative radiologic localizing studies, establishes that this technique should be performed in all adults with hyperinsulinemic hypoglycemia of unknown etiology.

Insulinomas have been shown to express GLP-1R in high density, and GLP-1R imaging has been used in some patients for localization of an insulinoma.[15] Fluorine-18-L-dihydroxyphenylalanine (18F-DOPA) positron emission tomography (PET) also has been used in localizing neuroendocrine tumors. 18F-DOPA PET has been found to be useful in some patients with insulinoma who had negative CT, MRI, and ultrasound results. Intraoperative manual palpation of the pancreas by an experienced surgeon and intraoperative ultrasonography are both sensitive methods with which to finalize the location of insulinomas.

Protein/Leucine Sensitivity Testing

Protein sensitivity is observed in some patients with congenital hyperinsulinemic hypoglycemia owing to mutations in the genes *ABCC8/KCNJ11*, *GDH*, and *HADH* that lead to protein-induced hypoglycemia. These patients will demonstrate severe hypoglycemia in response to a protein or leucine load.

Exercise Test

In some patients, exercise can trigger unregulated insulin secretion—a reaction referred to as exercise-induced hyperinsulinism. Promoter-activating mutations induce expression of the *SLC16A1* gene in β-cells, in which this gene is not usually transcribed, thereby permitting pyruvate uptake and pyruvate-stimulated insulin release despite ensuing hypoglycemia. An exercise test will identify this group of patients.

Genetic Studies

Genetic testing should be undertaken in children who have been diagnosed with congenital hyperinsulinemic hypoglycemia and other causes of hypoglycemia that might have a genetic basis. Mutation in the genes *ABCC8/KCNJ11* is the most common cause of medically unresponsive congenital hyperinsulinemic hypoglycemia. All patients with insulinoma and non-insulinoma islet cell tumors should be tested for mutations in the *MEN1/YY1* genes.

TREATMENT

Emergency Management

Acute management of hypoglycemia involves administration of oral glucose (dextrose gel)[A1,A2] if the patient is able to swallow. If patients cannot swallow, a bolus of intravenous glucose (in adults a bolus of 50% dextrose) should be given to correct the blood glucose level. Glucagon (1mg intramuscularly) can be used in the emergency management of hypoglycemia if the blood glucose level does not rise after giving intravenous glucose or if an intravenous cannula cannot be inserted. New nasal forms of glucagon are now available for the treatment of hypoglycemia,[16] but the intramuscular formulation is still recommended in this setting. Glucagon can cause rebound hypoglycemia, so the patient will need blood glucose monitoring after the administration of glucagon.

Management of Specific Causes of Hypoglycemia

The long-term management of hypoglycemia depends on the underlying cause, so establishing the correct diagnosis is fundamentally important.

Critical Illness–Associated Hypoglycemia

For critical illness–associated hypoglycemia, therapy focuses on treating sepsis, addressing any organ failure (especially liver failure), and making sure that no medications are contributing to the hypoglycemia.

Congenital Hyperinsulinemic Hypoglycemia

Diazoxide (5 to 20 mg/kg/day given orally three times daily) is the first-line medical therapy in children and adults with hyperinsulinemic hypoglycemia caused by congenital mutation. Fluid retention is a major side effect. Diazoxide may be combined with a diuretic (e.g., hydrochlorothiazide 25 to 50 mg daily in adults) to reduce the side effect of fluid retention. Second-line therapies include short-acting octreotide (5 to 35 μg/kg/day as an infusion or subcutaneous injections three or four times daily) or long-acting octreotide and glucagon (1 to 10 μg/kg/hour given as a subcutaneous or intravenous infusion). mTOR inhibitors (such as sirolimus, 0.5 mg/m^2/day given in one or two divided doses) have been tried as a last resort for patients who have diffuse forms of hyperinsulinemic hypoglycemia and who do not want to undergo a near total pancreatectomy.[17]

Insulinomas and Other Pancreatic Tumors

For adult patients with insulinoma, pancreatectomy is the treatment of choice (Chapter 213). However, insulinomas in adults may respond to therapy with diazoxide and octreotide (including long-acting octreotide). The mTOR inhibitor everolimus has been reported to be effective in controlling hypoglycemia in patients with malignant insulinomas or patients who cannot undergo surgical resection. Patients who have non–islet cell tumor hypoglycemia or IGF-2-omas also require resection of the primary tumor.

Postprandial Hypoglycemia and Dumping Syndrome

Conventional treatment approaches include acarbose, diazoxide, and octreotide. However, most of these options are either ineffective or limited by poor tolerance. Recently the use of calcium channel blockers and sodium glucose cotransporter-1 inhibitors (such as canagliflozin) has been described with some success. In some severe cases a pancreatectomy may be indicated.

Other Hypoglycemic Syndromes

The insulin autoimmune syndrome will respond to therapy with glucocorticoids (e.g., prednisolone starting at 0.5 mg/kg), but some patients have responded to diazoxide and octreotide. For tumor-associated hypoglycemia (Chapter 164), the localization and resection of the tumor is the treatment of choice. For drug- or toxin-induced hypoglycemia, the removal or avoidance of the responsible toxin is the treatment of choice.

Patients who have deficiencies of growth hormone or cortisol will require replacement therapy with recombinant growth hormone (e.g., between 0.02 to 0.03 μg/kg/day) and hydrocortisone (10 to 12 mg/m^2/day). Replacement therapy with glucocorticoids and mineralocorticoids can be life-saving in patients with adrenal insufficiency (Chapter 208).

Patients with hypoglycemia due to disorders of hepatic glycogen storage and release must avoid prolonged periods of fasting (Chapter 191). Raw, uncooked cornstarch is commonly used as a slow-release source of glucose and helps with prolonging the period of fasting.

For patients who have hypoglycemia due to defects in fatty acid oxidation, disorders of gluconeogenesis, and disorders of ketone body metabolism, the principles of treatment are similar to those already discussed. However, patients with fatty acid oxidation disorders should have carnitine supplementation (2 g by mouth daily in adults).

PROGNOSIS

For adults with insulinomas, pancreatectomy provides excellent long-term results, especially when the tumor can be completely removed.[18] The prognosis for other forms of hypoglycemia varies widely and depends on whether the underlying cause can be successfully addressed.

212 POLYGLANDULAR DISORDERS

LYNNETTE K. NIEMAN AND ALLEN M. SPIEGEL

DEFINITION

Polyglandular syndromes are disorders of dysfunction and pathology of more than one endocrine gland. These disorders can be classified into *neoplastic syndromes* with abnormal endocrine cell proliferation and often, but not invariably, hormone hypersecretion, and *autoimmune syndromes*, in which immune destruction of endocrine cells often results in hypofunction and reduced hormone secretion. Both the neoplastic and autoimmune polyglandular syndromes often have nonendocrine manifestations that are relatively syndrome specific. With the recent recognition of the many nonendocrine components of some autoimmune polyglandular syndromes, especially type 3, the term multiple autoimmune syndromes is increasingly being used.[1]

With few exceptions, the polyglandular syndromes are due to germline mutations of key growth regulatory genes (neoplastic syndromes)[2] or immune regulatory genes (autoimmune syndromes). These disorders must be differentiated from sporadic single–endocrine gland diseases for several reasons. First, recognition of a specific polyglandular syndrome should alert the clinician to look for other endocrine and extra-endocrine manifestations of the syndrome. Although some patients will present with multiple endocrine gland manifestations, some will initially present with only a single affected endocrine gland. Careful family history and screening for other endocrine and characteristic extra-endocrine manifestations are needed in such cases. Second, treatment of polyglandular disease may differ from treatment of individual gland disease. Third, because of the genetic basis of most of these syndromes, a careful family history and, in some cases, screening other family members to allow disease prevention in affected individuals are indicated.

This chapter discusses the best-characterized polyglandular disorders. Other chapters on the anterior pituitary (Chapter 205), thyroid (Chapter 207), adrenal cortex (Chapter 208), adrenal medulla (Chapter 209), pancreatic islets (Chapters 211 and 213), and parathyroids (Chapter 227) should be consulted for more detailed discussion of the diseases of individual glands.

EPIDEMIOLOGY

In the United States, the prevalence of multiple endocrine neoplasia type 1 (MEN 1) is estimated to be between 1 per 10,000 and 1 per 30,000. The total prevalence of MEN2A and B is estimated to be about 1 per 35,000.

NEOPLASTIC SYNDROMES

Seven distinct neoplastic syndromes involve more than one endocrine gland: MEN 1,[3] multiple endocrine neoplasia types 2A (MEN 2) and 2B (sometimes referred to as MEN 3),[4] multiple endocrine neoplasia type 4 (MEN 4),[5] multiple endocrine neoplasia type 5 (MEN 5),[6] Carney complex,[7] von Hippel-Lindau disease (VHL),[8] and McCune-Albright syndrome[9] (Table 212-1). Patients with polyglandular neoplastic syndromes typically present with their respective endocrine tumors at a younger age than patients with single-gland sporadic endocrine tumors.

All but McCune-Albright syndrome are caused by heterozygous germline mutations and are inherited in autosomal dominant fashion. The genes responsible for multiple endocrine neoplasia 1, 4, 5, Carney complex, and von Hippel-Lindau disease act as tumor suppressor genes. Germline loss-of-function mutations in one allele are followed by somatic mutations that inactivate the second normal allele, thereby leading to tumorigenesis. The basis for the tissue-specific expression of both the endocrine and extra-endocrine manifestations of these syndromes is not well understood, but the germline nature of the mutation and the expression of the affected gene in more than one endocrine gland explain the polyglandular aspect of the disorder. Multiple endocrine neoplasia 2A and 2B, in contrast, are caused by germline activating mutations of an oncogene, *RET*. The pattern of expression of this gene,

Multiple endocrine neoplasia 2A and 2B, in contrast, are caused by germline activating mutations of an oncogene, *RET*. The pattern of expression of this gene,

ABSTRACT

Polyglandular syndromes are disorders in which there is dysfunction and pathology of more than one endocrine gland. These may be either neoplastic syndromes, involving proliferation of various tissues and often a component of hyperfunction of endocrine glands, or they may be autoimmune syndromes in which immune destruction of tissues may result in loss of function. In general, these are genetic syndromes in which key growth regulatory genes (neoplastic disorders) or immune regulatory genes (autoimmune disorders) are mutated. Patients presenting with only one feature of these syndromes should be screened for the other features to ensure that all manifestations are treated and to enable screening of other family members or genetic counseling of the patient.

CNS = central nervous system; MEN = multiple endocrine neoplasia.

involving chromaffin cells, helps explain the specific clinical manifestations. McCune-Albright syndrome is caused by a somatic rather than germline mutation that constitutively activates the ubiquitously expressed *GNAS* gene. This mutation, which may occur early in embryogenesis, leads to unregulated cyclic adenosine monophosphate (cAMP) formation in affected cells. The resultant mosaic distribution of the mutant gene helps explain the pleiotropic manifestations of the disease.

TREATMENT

Treatment of the polyglandular neoplastic syndromes, both in terms of the neoplastic component and the hormone hypersecretion, poses greater challenges than treatment of individual endocrine tumors.[10] For disorders with high risk of fatal cancer, such as medullary thyroid cancer in multiple endocrine neoplasia 2, early genetic diagnosis and prophylactic surgical removal of the thyroid is indicated. In other disorders such as multiple endocrine neoplasia 1 and Carney complex, less aggressive approaches such as selective tumor resection and pharmacologic treatment to reduce hormone hypersecretion may be more appropriate. More detailed discussion of the clinical features, diagnosis, and treatment of these neoplastic syndromes may be found in other chapters (multiple endocrine neoplasia 1 in Chapter 227; multiple endocrine neoplasia 2 and 3 in Chapter 213; McCune-Albright syndrome in Chapters 214 and 217).

AUTOIMMUNE SYNDROMES

Organ-specific autoimmune disease, characterized by lymphocytic infiltration and organ-specific autoantibodies, commonly results in endocrine hypofunction. Not uncommonly, however, disorders of more than one endocrine gland appear in families or individual patients. Characteristic patterns of disease presentation and genetic inheritance allow the definition of two syndromes with overlapping manifestations (Table 212-2).[11]

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 1

DEFINITION

Autoimmune polyglandular syndrome type 1 is a rare disease that is also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy syndrome. It typically manifests in early childhood.

TABLE 212-2 CLINICAL FEATURES OF AUTOIMMUNE POLYGLANDULAR SYNDROMES

FEATURE	TYPE 1	TYPE 2
Mucocutaneous candidiasis	Very common	Not seen
Hypoparathyroidism	Common	Rare
Addison disease	Common	Common
Primary hypogonadism	Common	Occurs
Autoimmune thyroid disease	Rare	Common
Autoimmune diabetes	Occurs	Common
Alopecia	Common	Occurs
Keratopathy	Common	Not seen
Tympanic membrane calcification	Common	Not seen
Hypophysitis	Occurs	Occurs
Pernicious anemia	Occurs	Occurs
Vitiligo	Occurs	Occurs
Malabsorption syndrome	Occurs	Occurs as celiac disease
Autoimmune hepatitis	Occurs	Not seen
Autoimmune pneumonitis	Occurs	Not seen
Myasthenia gravis	Not seen	Occurs
Inheritance	Autosomal recessive	HLA association
Age at onset	Usually childhood	Usually adulthood

HLA = human leukocyte antigen.

PATHOBIOLOGY

Autoimmune polyglandular syndrome type 1 is an autosomal recessive disorder caused by a variety of inactivating mutations in the gene encoding autoimmune regulator-1 (AIRE-1),[12] which controls the expression of autoantigens by medullary epithelial cells of the thymus. These antigens are also expressed in peripheral tissues. Their expression in the thymus is important for negative selection (elimination) of autoreactive T cells, which underlies the development of (self-) tolerance. These autoreactive

T cells escape to the periphery in the absence of AIRE and, if activated, induce autoimmune destruction of the specific tissue. The appearance of organ-specific autoantibodies precedes disease presentation and predicts the development of specific end-organ damage. The role of these antibodies is unknown, however.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mucocutaneous candidiasis (Chapter 310) occurs in virtually all patients and is usually the first manifestation of disease.[13] Each of the disease components should be sought when any patient presents with hypoparathyroidism, primary adrenal insufficiency, or mucocutaneous candidiasis.

Hypoparathyroidism (Chapter 227) and Addison disease[14] (Chapter 208) are the most common endocrine manifestations; each of these diseases occurs in 70 to 80% of patients. Hypoparathyroidism usually precedes Addison disease; both diseases typically manifest before age 15 years. Premature ovarian failure (in 60% of affected women) usually presents as secondary amenorrhea; testicular failure occurs less frequently. Insulin-dependent diabetes mellitus occurs in 12% of patients, usually in adulthood; hypothyroidism is uncommon.

Nonendocrine components of this syndrome, in addition to the mucocutaneous candidiasis, include alopecia, vitiligo, ocular complications (e.g., keratitis, blepharitis, retinitis, corneal opacities, and ptosis), cerebellar ataxia, autoimmune hepatitis, enamel hypoplasia of teeth, tympanic membrane calcification, obstructive respiratory disease, nail dystrophy, parietal cell atrophy, vitamin B_{12} malabsorption, and more general intestinal malabsorption with steatorrhea. Asplenism, with Howell-Jolly bodies on peripheral blood smears (Fig. 154-3), has been noted in several patients. Pneumonitis, present in up to 40% of patients, may be underrecognized.

TREATMENT

The hypoparathyroidism is treated like the sporadic disease, with oral elemental calcium (500 to 1000 mg every 6 to 12 hours) and 1,25-dihydroxyvitamin D (e.g., calcitriol 0.25 to 2 mg daily), although variable intestinal malabsorption can present a particular therapeutic challenge. The goal is to maintain the serum calcium level in the low normal range, 8.0 to 8.5 mg/dL (2.0 to 2.1 nmol/L), to reduce the risk of iatrogenic kidney stones. Synthetic 1-84 parathyroid hormone (50 to 100 μg subcutaneously daily) can reduce the needed doses of calcium and vitamin D. The candidiasis usually can be satisfactorily controlled with topical ketoconazole for 1 to 2 weeks, with itraconazole oral solution if needed (Chapter 310). Primary adrenal insufficiency is treated with replacement of glucocorticoids and mineralocorticoids (see Chapter 208).

PROGNOSIS

The prognosis of the variably expressed hormonal disorders is similar to that of their sporadic counterparts. When the diagnosis of autoimmune polyglandular syndrome type 1 is made, surveys for other components of the syndrome can allow earlier treatment than would otherwise occur.

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPES 2, 3, AND 4

PATHOBIOLOGY

Autoimmune polyglandular syndrome types 2 and 3 are usually inherited in families with characteristic (normal) variants of genes that regulate the presentation of antigens to T cells and subsequent T-cell function. The most common genetic locus associated with this syndrome is the human leukocyte antigen (HLA) locus, particularly the B8, DR3, and DR4 alleles. The HLA associations do not predict disease absolutely, even in identical twins, so environmental or other genetic factors must influence disease presentation. Variants of the genes encoding cytotoxic T-lymphocyte antigen-4 (CTLA-4), the major histocompatibility complex class I chain-related gene A (MICA) allele 5.1, signal transducer and activator of transcription 4 (STAT4), and GATA binding protein 3 (GATA) can also predispose to Addison disease (autoimmune polyglandular syndrome type 2). The protein tyrosine phosphatase nonreceptor type 22 gene that encodes the lymphoid tyrosine phosphatase opposes signaling from the activated T-cell receptor. A variant of this gene is enriched in families with both type 1 diabetes mellitus and autoimmune thyroid disease. Genome-wide association studies have identified a large number of genes that are associated with type 1 diabetes and that influence immune responsiveness.

CLINICAL MANIFESTATIONS

Autoimmune polyglandular syndrome types 2 and 3 are considerably more common than type 1 and typically manifest in the fourth decade of life.[15] Insulin-dependent diabetes mellitus and thyroid dysfunction, either autoimmune hypothyroidism or Graves disease (Chapter 207), are the most frequent manifestations.[16] Addison disease (Chapter 208) is the third major endocrine component of this disorder, which is present only in autoimmune polyglandular syndrome type 2. Although most patients who present with autoimmune diabetes or thyroid disease have clinical involvement of only one gland, many patients with autoimmune Addison disease develop clinically evident disease in other endocrine glands. Less common components of type 2 or 3 autoimmune polyglandular syndrome include primary hypogonadism and hypophysitis. Pernicious anemia, vitiligo, celiac disease, alopecia, and myasthenia gravis (Chapter 390) are also associated with this syndrome. Additional autoimmune nonendocrine disorders in autoimmune polyglandular syndrome type 3 affect the gastrointestinal tract, pancreas, skin, and heart, as well as the hepatobiliary, nervous, and hematologic systems, and have led to the alternative term multiple autoimmune syndromes type 3.

Autoimmune polyglandular syndrome type 4 is a combination of endocrine and autoimmune diseases, including insulin-dependent diabetes, pernicious anemia, alopecia, vitiligo, or neuromuscular junction disorder but without Addison disease, thyroid disease, or hypoparathyroidism. A substantial proportion of these patients also may have positive autoantibodies against glutamic acid decarboxylase.

Organ-specific antibodies appear before clinical disease and predict subsequent disease. The role of these antibodies in organ hypofunction has not been established, however.

DIAGNOSIS

Thyroid hormone therapy can precipitate symptoms of adrenal insufficiency in patients with both disorders. Consequently, a careful history (including family history), physical examination, and a low threshold for specific laboratory testing for adrenal insufficiency should be part of the evaluation of every patient with autoimmune hypothyroidism. Further, combinations of hypothyroidism, adrenal insufficiency, and hypogonadism can mimic hypopituitarism, although specific hormonal testing (Chapter 205) can easily distinguish these disorders. Because multiple components of the syndrome can appear asynchronously, periodic evaluation for the early appearance of additional disease components is indicated.

TREATMENT

The treatment of each component of this syndrome is identical to the treatment of each disorder in isolation.

PROGNOSIS

The prognosis of the individual components of autoimmune polyglandular syndrome types 2 and 3 is the same as for the sporadic versions of each component.

213 NEUROENDOCRINE NEOPLASMS

EDWARD M. WOLIN AND ROBERT T. JENSEN

DEFINITION

Neuroendocrine neoplasms,[1,2] formerly called neuroendocrine tumors, are now subclassified as well-differentiated neuroendocrine tumors and poorly differentiated neuroendocrine carcinomas. This new division has important implication for both prognosis and treatment. Neuroendocrine neoplasms occur in almost all tissues but have historically been divided into two large groups, pancreatic neuroendocrine neoplasms/tumors compared with neuroendocrine neoplasms in other locations, often called carcinoid tumors in older classifications.

EPIDEMIOLOGY

The annual incidence of neuroendocrine neoplasms in the United States is estimated to be about 12,000, a with prevalence of about 175,000. About 50% occur in the gastrointestinal tract, 20% in the lung, and 12% with an unknown primary.[3] Pancreatic neuroendocrine tumors account for 1 to 10% of all diagnosed pancreatic neoplasms, with a prevalence of 1 per 100,000 and an annual incidence of 1 to 4 per million. However, pancreatic neuroendocrine neoplasms are seen in 0.5 to 1.5% of autopsies, thereby indicating that the vast majority are not clinically evident. About 60 to 80% of all pancreatic neuroendocrine neoplasms are nonfunctioning (Table 213-1). Among functional pancreatic neuroendocrine neoplasms, insulinomas and gastrinomas are the most common, with annual incidences of 0.5 to 3 per million. In general, insulinomas and gastrinomas are 8-fold more frequent than VIPomas,17-fold more frequent than glucagonomas, and greater than 20-fold more frequent than the others.

PATHOBIOLOGY

Pathology/Classification

Neuroendocrine neoplasms originate from the diffuse neuroendocrine system, which is present throughout the body. All neuroendocrine neoplasms share cytologic features of an endodermal origin. Ultrastructurally, these neoplasms have electron-dense granules that contain multiple peptides/amines, neuron-specific enolase, synaptophysin, and chromogranins. Histologically, they characteristically show small cells with uniform nuclei

TABLE 213-1 PANCREATIC NEUROENDOCRINE NEOPLASMS (pNENs)

NAME OF TUMOR	NAME OF SYNDROME	MAIN SIGNS OR SYMPTOMS	LOCATION (%)	MALIGNANCY (%)	HORMONE CAUSING SYNDROME
I. FUNCTIONAL pNEN					
Gastrinoma	Zollinger-Ellison syndrome	Abdominal pain, diarrhea, esophageal symptoms	Pancreas—10-30 Duodenum—70-90 Other—0-10	60-90	Gastrin
Insulinoma	Insulinoma	Hypoglycemic symptoms	Pancreas—100	5-15	Insulin (Chapter 211)
Glucagonoma	Glucagonoma	Dermatitis, diabetes/ glucose intolerance, weight loss	Pancreas—100	60	Glucagon
VIPoma	Verner-Morrison, Pancreatic cholera, WDHA	Severe watery diarrhea, hypokalemia	Pancreas—90 Other—10 (neural, adrenal, periganglionic tissue)	80	Vasoactive intestinal peptide (VIP)
Somatostatinoma	Somatostatinoma	Diabetes mellitus, cholelithiasis, diarrhea	Pancreas—56 Duodenum/jejunum—44	60	Somatostatin
GRFoma	GRFoma	Acromegaly	Pancreas—30 Lung—54 Jejunum—7 Other—13 (adrenal, foregut, retroperitoneum)	30	Growth hormone–releasing factor (GRF)
ACTHoma	ACTHoma	Cushing syndrome	Pancreas—4-16 of all ectopic Cushing syndrome cases	>95	Adrenocorticotropic hormone (ACTH)
pNEN causing carcinoid syndrome	pNEN causing carcinoid syndrome	Diarrhea, flushing	Pancreas—<1 of all carcinoids	60-90	Serotonin, tachykinins
pNEN causing hypercalcemia	pNEN causing hypercalcemia	Signs/symptoms of hypercalcemia	Pancreas (rare cause of hypercalcemia)	>85	PTHrP, other unknown
pNEN secreting erythropoietin	pNEN secreting erythropoietin	Polycythemia	Pancreas	Unknown	Erythropoietin
pNEN secreting renin	pNEN secreting renin	Hypertension	Pancreas	Unknown	Renin
pNEN secreting luteinizing hormone syndrome	pNEN secreting luteinizing hormone	Masculinization, loss of libido	Pancreas	Unknown	Luteinizing hormone
CCKoma	CCKoma	Diarrhea, peptic ulcer, gallstone	Pancreas	Unknown	Cholecystokinin
pNEN secreting enteroglucagon	pNEN secreting enteroglucagon	Small intestinal hypertrophy	Pancreas, renal, duodenal	Unknown	Enteroglucagon
pNEN secreting IGF-2 or GLP-1	pNEN secreting IGF-2 or GLP-1	Hypoglycemic symptoms	Pancreas	Unknown	IGF-2/GLP-1
pNEN secreting secretin	Secretinoma	Diarrhea	Pancreas	Unknown	Secretin
II. NF-pNEN					
NONFUNCTIONAL/ PPoma	NONFUNCTIONAL/ PPoma	Weight loss, abdominal mass, hepatomegaly	Pancreas—100	60-90	None: pancreatic polypeptide, chromogranin released but no known symptoms due to hypersecretion

CCKoma = cholecystokinin-secreting NEN; Duod = duodenum; GLP-1 = glucagon-like peptide 1; IGF-2 = insulin-like growth factor-II; pNEN = pancreatic neuroendocrine neoplasm; PP = pancreatic polypeptide; PPoma = pancreatic polypeptide secreting NEN; PTHrP = parathormone-related peptide; WDHA = watery diarrhea, hypokalemia, and achlorhydria.

ABSTRACT

This chapter summarizes all important aspects of neuroendocrine neoplasms, including their epidemiology; pathogenesis; localization methods, including molecular imaging; and latest treatments. It also includes brief summaries and updates on the most important functional pancreatic endocrine tumor syndromes, carcinoid syndrome, and carcinoid tumors in the most frequent locations.

and low rates of mitotic figures. Chromogranin immunoreactivity in the tumor is now widely used to identify them as neuroendocrine neoplasms. Malignancy can be determined reliably only by demonstrating the presence of metastatic disease.

Classification systems for staging and grading neuroendocrine neoplasms consider the neoplasm's differentiation[4] (good vs. poor), tumor size, invasion, and extent. The neuroendocrine neoplasms are also divided into three grades depending on proliferative indices, including mitotic rate and the expression of Ki-67. An important differentiation is between the well-differentiated neuroendocrine neoplasms as compared with the poorly differentiated neuroendocrine carcinomas.[5]

Molecular Pathogenesis

Unlike nonendocrine tumors, neuroendocrine neoplasms rarely have mutations of common oncogenes (*ras, fos, myc,* etc.) or common tumor suppressor genes *(p53, rb)*. Pancreatic neuroendocrine neoplasms, gastrointestinal neuroendocrine neoplasms, and lung neuroendocrine neoplasms all have a different molecular pathogenesis. Furthermore, the pathogenesis is different for well-differentiated neuroendocrine tumors as compared with poorly differentiated neuroendocrine carcinomas.

Pancreatic neuroendocrine neoplasms most commonly have allelic losses at chromosomal loci 1p, 1q, 3p, 11p, and 22p. Somatic mutations in pancreatic neuroendocrine neoplasms are commonly found in four main pathways, including genes involved in chromatin remodeling, DNA repair, mammalian target of rapamycin (mTOR) signaling, and telomere maintenance. Sequencing studies of pancreatic neuroendocrine neoplasms show that 44% have inactivating mutations of the multiple endocrine neoplasia type 1 gene *(MEN1),* 43% have mutations in genes encoding either of two subunits of a transcription/chromatin remodeling complex composed of DAXX (death domain–associated protein) and ATRX (α-thalassemia/intellectual disability syndrome X-linked chromatin remodeler), and 14% have mutations in the mTOR pathway.

Gastrointestinal neuroendocrine neoplasms usually have losses at chromosomal loci 18q, 18p, 9p, and 16q. For small intestinal carcinoids, sequencing studies demonstrate a low mutation rate, with recurrent somatic mutations and deletions in *CDKN1B*, which is the cyclin-dependent kinase inhibitor gene that encodes p27, in 8% of tumors.

In contrast, neuroendocrine carcinomas have distinctive activations in tumor protein 53 (TP53) and retinoblastoma gene *(RB1)*. Recent studies suggest that epigenetic dysregulation may play an important role in the pathogenesis of neuroendocrine neoplasms.[6]

Four autosomal dominant inherited disorders are associated with pancreatic neuroendocrine neoplasms: MEN1 (in 80 to 100% of patients); von Hippel-Lindau disease (VHL; in 10 to 17% of patients); tuberous sclerosis (in 0.5% of patients); and von Recklinghausen disease (neurofibromatosis-1; 12% develop duodenal somatostatinomas).[7] Familial syndromes associated with carcinoids are uncommon.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of neuroendocrine neoplasms depend on whether the tumor is functional and secretes a biologically active peptide or whether it is nonfunctional and causes symptoms via a mass effect from the tumor. Diagnosis relies on biochemical testing to detect the hormonal excess as well as imaging, endoscopic, and pathologic studies to localize the tumors and identify its neuroendocrine nature.[8]

To assess the primary location and extent of a neuroendocrine neoplasm, the initial tumor localization study is generally a cross-sectional imaging examination, such as triphasic computed tomography (CT) or magnetic resonance imaging (MRI) with contrast.[9] More than 90% of well-differentiated neuroendocrine neoplasms overexpress one of the five subtypes of somatostatin receptors (sst1-5), with sst2 the most frequently overexpressed (>80%). Somatostatin receptor imaging using radiolabeled somatostatin analogues with high affinity for sst2 is now the most sensitive imaging modality. The most frequently used modality is ^{68}Ga-DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)–labeled somatostatin analogues with positron emission tomography combined with CT (PET/CT) or MRI (PET/MRI).

Endoscopic studies are particularly important for localizing duodenal, gastric, and rectal neuroendocrine neoplasms. Endoscopic ultrasound is widely used to localize pancreatic neuroendocrine neoplasms and to assess the depth of penetration of gastric and rectal neuroendocrine neoplasms.

TREATMENT

Treatment should be initiated urgently in patients who have to address a heavy tumor burden with mass-related symptoms, symptoms related to an uncontrolled functional tumor,[10] compromised liver function, poorly differentiated or high-grade tumor, or rapid growth on imaging. Conversely, treatment has little urgency if tumors have small volume, are low grade, and are asymptomatic.

For patients with neuroendocrine neoplasms, two treatment issues must be addressed. First, any excess hormone state must be controlled; and second, treatment must be directed against the tumor itself because of its frequently malignant nature. Surgical resection can solve both problems, but unfortunately many patients present with disease that is advanced and unresectable.

SPECIFIC NEUROENDOCRINE NEOPLASMS

PANCREATIC NEUROENDOCRINE NEOPLASMS

Pancreatic neuroendocrine neoplasms are also called islet-cell tumors, but this latter term is also a misnomer because 7 different neoplasms (see Table 213-1) can occur outside the pancreas.[11] Several of the functional neuroendocrine syndromes are very uncommon (<5 cases reported), including neuroendocrine neoplasms that secrete renin, erythropoietin, enteroglucagon, luteinizing hormone, secretin, cholecystokinin, glucagon-like peptide-1 (GLP-1), and insulin-like growth factor-II. In addition, pancreatic neuroendocrine neoplasms can also synthesize neurotensin, calcitonin, and ghrelin, but no related syndromes have been established. Except for insulinomas, pancreatic neuroendocrine neoplasms are frequently malignant (>50%).

FUNCTIONAL PANCREATIC NEUROENDOCRINE NEOPLASMS

ZOLLINGER-ELLISON SYNDROME (GASTRINOMAS)

Zollinger-Ellison syndrome is a clinical syndrome caused by a gastrin-secreting neuroendocrine neoplasm that is usually located in the pancreas or duodenum. The syndrome is characterized by clinical symptoms and signs that result from hypersecretion of gastric acid: peptic ulcer disease, diarrhea, and esophageal reflux disease.

Zollinger-Ellison syndrome has an annual incidence of 0.5 to 2 per million. It is diagnosed most frequently between ages 35 and 65 years, but has been reported in both children and the elderly.

PATHOBIOLOGY

Gastrinomas are found in the duodenum (80 to 100%) more frequently than in the pancreas (0 to 20%). Duodenal gastrinomas are generally small (<1 cm), whereas pancreatic gastrinomas are generally larger. Occasionally Zollinger-Ellison syndrome results from a gastrinoma in the splenic hilum, mesentery, stomach, or only in a lymph node or an ovary. Extra-gastrointestinal gastrinomas producing Zollinger-Ellison syndrome have been reported in the heart and with small cell lung cancer (Chapter 177).

Gastrin stimulates parietal cells to secrete acid and has a growth effect on the gastric mucosa. Chronic hypergastrinemia leads to increased gastric mucosal thickness, prominent gastric folds, and increased numbers of parietal cells and gastric enterochromaffin-like cells. Patients with gastrinomas have increased basal and maximal acid outputs from the stomach. *Helicobacter pylori* appears not to be important in the pathogenesis of the ulcer disease in Zollinger-Ellison syndrome, in contrast to common peptic ulcers (Chapter 125). Diarrhea is common because the large-volume gastric acid output leads to structural damage to the small intestine (inflammation, blunted villi, edema), interference with fat transport, inactivation of pancreatic lipase, and precipitation of bile acids. These same mechanisms, if prolonged, can lead to steatorrhea. If acid hypersecretion is controlled, the diarrhea will stop.

From 20 to 25% of Zollinger-Ellison syndrome patients have MEN1 (MEN1/Zollinger-Ellison syndrome) (Chapter 125). These patients have hyperplasia or tumors of multiple endocrine glands (parathyroid hyperplasia [>90%], pituitary tumors [60%]). In MEN1/Zollinger-Ellison syndrome patients, 80 to 95% of the gastrinomas are in the duodenum, where they are frequently small (<0.5 cm), almost always multiple, and associated with lymph node metastases in 40 to 60% of cases.

CLINICAL MANIFESTATIONS

Abdominal pain resulting from a peptic ulcer is the most common symptom (>80%). Most ulcers occur in the duodenum (>85%), but they occasionally

occur in the postbulbar area, jejunum, or stomach, or in multiple locations. Initially, the pain is usually like that of patients with typical peptic ulcer disease (Chapter 125). With time, however, the symptoms become persistent and generally respond poorly to treatments aimed at eliminating *H. pylori* and to conventional doses of histamine-2 receptor antagonists. By comparison, conventional doses of proton pump inhibitors (e.g., omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole; Table 124-1) frequently control the symptoms of most patients with Zollinger-Ellison syndrome.

Heartburn is also common (20%). Diarrhea (60 to 70%) occurs frequently and may be the first symptom (10 to 20%). In MEN1, Zollinger-Ellison syndrome is the most common functional syndrome (55%), although patients typically first develop renal stones (Chapter 111) related to hypercalcemia from the associated hyperparathyroidism (Chapter 227) or have elevated prolactin levels resulting from pituitary tumors that only develop later.

Almost all the initial symptoms of Zollinger-Ellison syndrome result from the effects of acid hypersecretion, but patients can have tumor-related symptoms late in the disease. Approximately one third of patients have metastatic liver disease at presentation, but less than 20% of other patients develop metastatic disease to the liver during a 10-year follow-up period.

Up to 5% of patients with Zollinger-Ellison syndrome develop ectopic Cushing syndrome (Chapter 208) because the gastrinoma secretes adrenocorticotropic hormone (ACTH). These patients usually have a metastatic gastrinoma in the liver, have Zollinger-Ellison syndrome without MEN1, and have a poor prognosis.

DIAGNOSIS

Zollinger-Ellison syndrome should be suspected in any patient whose peptic ulcer disease is accompanied by diarrhea, is recurrent, does not heal with treatment, is not associated with *H. pylori* infection, is associated with a complication (bleeding, obstruction, esophageal stricture), is multiple, occurs in unusual locations, or is associated with a pancreatic tumor. Zollinger-Ellison syndrome also should be suspected in patients who have chronic secretory diarrhea (Chapter 126), as well as when peptic ulcer disease is associated with large gastric folds, a family/personal history of nephrolithiases/endocrinopathies, or the finding of hypercalcemia, hypergastrinemia, or acid hypersecretion.

When suspected, the initial test is a fasting serum gastrin level, which is elevated in 99 to 100% of patients with Zollinger-Ellison syndrome. Besides Zollinger-Ellison syndrome, other causes of fasting hypergastrinemia include conditions that also are associated with hyperchlorhydria (e.g., retained antrum, antral hyperfunction/hyperplasia, renal failure, *H. pylori* infections) and conditions that are associated with hypochlorhydria or achlorhydria (e.g., physiologic hypergastrinemia in pernicious anemia, atrophic gastritis, or the use of proton pump inhibitors or histamine-2 antagonists). If the serum gastrin level is elevated, a fasting gastric pH should be determined. If the serum gastrin is greater than 1000 pg/mL (normal <100) and the gastric pH is less than 2.0, the patient almost certainly has the Zollinger-Ellison syndrome. If the gastrin level is increased less than 10-fold above normal and the gastric pH is less than 2.0, basal acid output should be measured and a secretin test (see Table 126-6) should be performed. More than 95% of patients with Zollinger-Ellison syndrome have a basal acid output greater than 15 mEq/hour if no previous gastric acid–reducing surgery has been performed, and 94% have a positive secretin test (a >120 pg/mL stimulated increase in serum gastrin). If possible, proton pump inhibitors should be discontinued for up to 1 week to ensure that the cause of the hypergastrinemia is not the drug itself. Since discontinuing a proton pump inhibitor in a patient with undiagnosed Zollinger-Ellison syndrome can lead to complications of peptic ulcer disease, this approach should be undertaken with care and preferably by expert physicians who are well versed in making this diagnosis.

Differential Diagnosis

A positive secretin test in a patient who is not taking proton pump inhibitors or histamine-2 antagonists excludes other causes of hypergastrinemia and hyperchlorhydria that may mimic the Zollinger-Ellison syndrome. In all patients with Zollinger-Ellison syndrome, evaluation must exclude MEN1 syndrome by searching for other endocrinopathies and assessing the family history.

TREATMENT

Medical Therapy

Patients require medical therapy directed at controlling the gastric acid hypersecretion and, if possible, surgical therapy to remove the gastrinoma.[12] Proton pump inhibitors (Table 124-1), which are the drugs of choice, can control hypersecretion in almost every patient. The recommended starting dose is omeprazole 60 mg once a day. In 30% of patients, higher doses or more frequent doses are needed, particularly in patients with complicated disease (e.g., MEN1, previous gastric surgery, or a history of severe esophageal reflux). With time, the omeprazole dose can be reduced in most patients with uncomplicated disease to 20 to 40 mg/day. Patients must be treated indefinitely unless surgically cured. Long-term therapy is generally safe, and patients have been treated for up to 20 years with omeprazole without loss of efficacy, although reduced vitamin B_{12} levels may be a side effect that requires treatment (Chapter 150). Histamine-2 receptor antagonists (Table 124-1) are also effective, but frequent (every 4 to 6 hours), and high doses are needed. Long-acting somatostatin analogs can also control the acid hypersecretion but are uncommonly used because parental administration is needed, whereas proton pump inhibitors are effective with oral dosing.

Surgical Therapy

Surgical exploration for cure is recommended in all patients who do not have unresectable liver metastases, MEN1, or complicating medical conditions that limit life expectancy.[13] Tumors are found by experienced endocrine surgeons in 95% of patients at surgery. At exploration, a duodenotomy to locate small duodenal gastrinomas is essential, as is the use of operative ultrasound to find and stage small pancreatic tumors. Surgical treatment of MEN1/Zollinger-Ellison syndrome patients is controversial, because 80 to 90% have multiple small duodenal tumors; 50 to 60% of patients have metastatic lymph nodes and cannot be cured without extensive resections (usually a Whipple procedure).

Total gastrectomy is now performed only in patients who cannot or will not take oral antisecretory medications. Parathyroidectomy should be performed in MEN1 patients with hyperparathyroidism and Zollinger-Ellison syndrome because the procedure reduces acid secretion and increases the sensitivity to antisecretory drugs.

Metastatic Disease

If the metastatic disease can be resected, surgery should be considered (5 to 15% of cases). Otherwise, however, treatment of advanced disease is as for other advanced pancreatic neuroendocrine neoplasms (see later).

PROGNOSIS

MEN1/Zollinger-Ellison syndrome patients with an imaged tumor that is less than 2 to 2.5 cm have an excellent prognosis without surgery.[14] Approximately 25% of gastrinomas, however, show aggressive growth. Surgical resection decreases the metastatic rate, increases survival, and results in a 5-year cure rate of 30 to 40%. Patients with metastatic gastrinoma in the liver have a poor prognosis, with a 5-year survival rate of 30%. The presence of advanced gastrinoma grade or stage, large primary tumor, a pancreatic tumor, bone metastases, development of ectopic Cushing syndrome, or a high fasting gastrin level is associated with aggressive growth.

GLUCAGONOMAS

Glucagonomas are pancreatic neuroendocrine neoplasms that ectopically secrete glucagon, thereby causing a specific syndrome that includes glucose intolerance and unique dermal manifestations.

Glucagonomas have an annual population incidence of about 1 per 10 to 100 million. Patients typically present in their fifth decade. In many series, patients present late with large primary tumors, and more than 50 to 80% are metastatic at presentation.

PATHOBIOLOGY

The hypersecretion of glucagon causes glucose intolerance. The exact origin of the rash (necrolytic migratory erythema) is unclear. Some data suggest that prolonged glucagon infusions can cause the characteristic skin lesions. Zinc deficiency may play a role because the rash is similar to what can be seen with zinc deficiency (acrodermatitis enteropathica) and because the rash improves in some patients who are given zinc. The hypo-aminoacidemia is thought to be secondary to the effect of glucagon on amino acid metabolism by altering gluconeogenesis. Wasting and weight loss, which are intrinsic components of the glucagonoma syndrome, may be caused by an anorectic substance distinct from glucagon.

CLINICAL MANIFESTATIONS

The cardinal clinical features are a distinct dermatitis (necrolytic migratory erythema, seen in 70 to 90% of patients; Fig. 213-1), glucose intolerance or diabetes mellitus (40 to 90% of patients), weight loss (70 to 96% of patients), anemia (30 to 85% of patients), hypoaminoacidemia (80 to 90% of patients) with deficiencies of essential fatty acids, thromboembolism (10 to 25%), diarrhea (15 to 30%), and psychiatric disturbances (0 to 20%).[15] Necrolytic migratory erythema is usually found at intertriginous and periorificial sites, especially in the groin and buttocks. It is initially erythematous, becomes raised, and develops central bullae whose tops detach, with the eroded areas becoming crusty. Healing occurs with hyperpigmentation.

DIAGNOSIS

The diagnosis is established by demonstrating elevated plasma glucagon levels with accompanying symptoms and signs. Normal glucagon levels are 150 to 200 pg/mL, but patients with glucagonomas usually (60 to 90%) have levels greater than 1000 pg/mL. Increased plasma glucagon levels also occur in renal insufficiency, acute pancreatitis, hypercorticolism, hepatic diseases, celiac disease, severe stress, and prolonged fasting; in patients treated with danazol; and in familial hyperglucagonemia. In these conditions the level is usually less than 500 pg/mL except in patients with hepatic diseases or in those with familial hyperglucagonemia. Necrolytic migratory erythema is not specific for glucagonomas and is also seen in short bowel syndrome, myelodysplastic syndromes, malnutrition, hepatitis B infections, cirrhosis, celiac disease, other malignancies, inflammatory bowel disease, and nutritional deficiencies.

Mahvash disease is characterized by mutations in the glucagon receptor gene, glucagon cell hyperplasia, and hyperglucagonemia, but without the symptoms of the glucagonoma syndrome. Glucagon cell adenomatosis is characterized by glucagon cell hyperplasia and occasional symptoms that mimic the glucagonoma syndrome.

FIGURE 213-1. A patient with a glucagonoma with the characteristic rash (necrolytic migratory erythema). The rash is usually at intertriginous areas or periorificial sites and shows various stages of erythema and crusting (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London. Mosby; 2003.)

Glucagonomas are generally large when discovered (mean, 5 to 10 cm), and they most frequently occur in the pancreatic tail (>50%). Liver metastases are commonly present at the time of diagnosis (45 to 80%).

TREATMENT

Subcutaneous monthly administration of a synthetic long-acting somatostatin analogues, octreotide (octreotide [LAR], 10 to 30 mg intramuscularly every 4 weeks or lanreotide, 90 to 120 mg deep subcutaneous injection monthly controls the rash in 80% of patients and improves weight loss, diarrhea, and hypoaminoacidemia. However, it usually does not improve the diabetes mellitus. Zinc supplementation (440 mg daily) and infusions of amino acids, fatty acids, or both under expert care can diminish the severity of the rash. After tumor localization, surgical resection is preferred; even debulking of metastatic tumor may be of benefit. For advanced, nonresectable disease, treatment is as for other pancreatic neuroendocrine neoplasms (see later).

PROGNOSIS

The prognosis is largely determined by the growth of the tumor per se because the symptoms of glucagon excess can be largely controlled by somatostatin analogues. The mean 5-year survival rate is 50%, but extended survivals (>15 years) are reported in some patients who are treated with somatostatin analogs and other tumor-directed therapies.

VIPOMAS

The VIPoma syndrome, also called the Verner-Morrison syndrome, pancreatic cholera, and the WDHA syndrome (for watery diarrhea, hypokalemia, and achlorhydria), results from a neuroendocrine neoplasm, usually in the pancreas, that ectopically secretes vasoactive intestinal polypeptide (VIP).[16] The annual incidence is about 1 per million population.

PATHOBIOLOGY

VIPomas in adults are found in the pancreas in 80 to 90% of cases; rare cases result from intestinal carcinoids, ganglioneuromas, ganglioneuroblastomas, and pheochromocytomas. In children younger than 10 years and rarely in adults, the VIPoma syndrome is caused by ganglioneuromas or ganglioneuroblastomas at extrapancreatic sites. VIPomas are usually large and solitary; 50 to 75% occur in the pancreatic tail, and 40 to 70% have metastasized at the time of diagnosis. VIPomas frequently secrete both VIP and peptide histidine methionine, but VIP is responsible for the symptoms. VIP is a potent stimulant of secretion in the small and large intestine. VIP also causes relaxation of gastrointestinal smooth muscle, thereby contributing to the dilated loops of bowel and atonic gallbladder that are common in this syndrome. Hypochlorhydria is thought to result from the inhibitory effect of VIP on gastric acid secretion, the flushing is related to the vasodilatory effects of VIP, and the hyperglycemia is caused by the glycogenolytic effect of VIP. The mechanism of the hypercalcemia remains unclear.

CLINICAL MANIFESTATIONS

The cardinal clinical feature is severe, large-volume, watery diarrhea (>1 L/day) that is secretory and occurs during fasting. Hypokalemia (67 to 100%) and dehydration (83%) commonly occur because of the volume of the diarrhea. Achlorhydria is only occasionally noted, but hypochlorhydria is usually found (34 to 72% of cases). Flushing occurs in 20% of patients, hyperglycemia in 40 to 50%, and hypercalcemia in 41 to 50%. Steatorrhea is uncommon (16%) despite the volume of diarrhea.

DIAGNOSIS

The diarrhea of VIPomas characteristically persists during fasting and is large in volume (>3 L/day in 70 to 80%); the diagnosis is excluded when fasting stool volume is less than 700 mL/day. To differentiate VIPomas from other causes of large-volume fasting diarrhea, fasting plasma VIP levels should be determined. The normal value in most laboratories is less than 190 pg/mL, and elevated levels are detected in 90 to 100% of patients. The differential diagnosis of large-volume fasting diarrhea (>700 mL/day) includes Zollinger-Ellison syndrome, diffuse islet cell hyperplasia, surreptitious use of laxatives, the pseudopancreatic cholera syndrome, and, rarely, human immunodeficiency virus (HIV) infection (Chapter 359). Serum gastrin levels identify patients with Zollinger-Ellison syndrome, and plasma VIP levels are normal in most patients who abuse laxatives, in 82% of patients with pancreatic islet cell hyperplasia, and in patients with HIV-induced secretory diarrhea.

TREATMENT

The symptoms caused by the VIP are controlled initially in more than 85% of patients by daily doses of octreotide (50 to 400 μg 1 to 3 times daily) or by monthly injections of a depot form (octreotide [LAR] 10 to 30 mg intramuscularly every 4 weeks or lanreotide 90 to 120 mg deep subcutaneous injection monthly), but increased doses guided by experts may be needed over time. After tumor localization studies, surgical resection should be attempted if it is possible to remove all visible tumor; however, more than 50% of patients have generalized liver metastases at diagnosis, so complete resection may not be possible. For patients with unresectable advanced disease, treatment is similar to that for other advanced nonresectable pancreatic neuroendocrine neoplasms. In most refractory cases with advanced VIPomas, the diarrhea can be controlled with peptide receptor radionuclide therapy (see later).

PROGNOSIS

The prognosis is largely determined by the growth of the tumor per se, because the symptoms of VIP excess usually can be controlled by somatostatin analogues, antitumor treatments, or peptide receptor radionuclide therapy. The mean 5-year survival rate is 50 to 70%.

SOMATOSTATINOMAS

Somatostatinomas are neuroendocrine neoplasms that have an annual incidence of about 1 per 40 million individuals. They occur primarily in the pancreas or upper small intestine and ectopically secrete somatostatin.[17] In the gastrointestinal tract, somatostatin inhibits basal and stimulated gastric acid secretion, pancreatic secretion, intestinal absorption of amino acids, gallbladder contractility, and release of numerous hormones, including cholecystokinin and gastrin.

CLINICAL MANIFESTATIONS

The somatostatinoma syndrome includes diabetes mellitus, gallbladder disease, diarrhea, steatorrhea, and weight loss. However, most somatostatinomas do not cause these symptoms and are diagnosed incidentally.

Pancreatic somatostatinomas occur in the pancreatic head in 60 to 80% of cases. They are usually large (mean 5 cm) and solitary, but about 70 to 90% have metastasized at the time of diagnosis. In contrast, duodenal somatostatinomas (20 to 40% of cases) are smaller (mean, 2.4 cm), frequently associated with psammoma bodies on histologic examination (11%), and less frequently have metastases at diagnosis (30 to 40%).

The distinct somatostatinoma syndrome, which occurs much more commonly in patients with pancreatic than duodenal or intestinal somatostatinomas, includes diabetes, gallbladder disease, diarrhea, steatorrhea, and weight loss. Duodenal somatostatinomas occur in up to 10% of patients with von Recklinghausen disease and are usually asymptomatic.

DIAGNOSIS

Somatostatinomas are usually found incidentally, particularly during exploratory laparotomy, cholecystectomy, endoscopy, or on imaging studies. The presence of psammoma bodies on histologic examination of a duodenal neuroendocrine tumor or any duodenal lesions in patients with von Recklinghausen disease should raise the suspicion of a duodenal somatostatinoma. Somatostatinomas (primarily duodenal) are also associated with the rare, inherited syndrome polycythemia–paraganglioma/pheochromocytoma–somatostatinoma.

The diagnosis of the somatostatinoma syndrome requires the demonstration of increased concentrations of somatostatin-like immunoreactivity in the plasma and the resected tumor. However, other neoplasms outside the pancreas or intestine, such as small cell lung cancer, medullary thyroid carcinoma, pheochromocytomas, and paragangliomas, also may have elevated concentrations of somatostatin-like immunoreactivity. Somatostatinomas can be imaged using somatostatin receptor scintigraphy or, if needed, other conventional imaging studies to assess the tumor's location.

TREATMENT

Treatment with octreotide (10 to 30 mg intramuscularly every 4 weeks) or lanreotide (90 to 120 mg deep subcutaneous injection monthly) can improve symptoms. Surgery should be performed if possible. For patients with unresectable advanced disease, treatment is similar to treatment for other advanced nonresectable pancreatic neuroendocrine neoplasms (see later).

PROGNOSIS

Patients who have intestinal somatostatinomas, which uncommonly cause the somatostatinoma syndrome and are less malignant, have an excellent prognosis (5-year survival rate >80%). By comparison, patients who have pancreatic somatostatinomas, which frequently cause the somatostatinoma syndrome and present with metastatic disease (>70%), have a much reduced 5-year survival rate (<50%).

GROWTH HORMONE–RELEASING FACTOR NEOPLASMS

Growth hormone–releasing factor secreting neuroendocrine neoplasms (GRFomas) are rare tumors that can originate in the pancreas, but they also can occur in other extrapancreatic locations. The growth hormone-releasing factor may cause acromegaly that is clinically indistinguishable from that caused by a pituitary adenoma (Chapter 205).

GRFomas most commonly occur in the lung (about 55%). Most of the remainder occur in the gastrointestinal tract, including 30% in the pancreas. Pancreatic GRFomas are usually large (mean, 6 cm), 40% are metastatic at diagnosis, 40% occur in combination with Zollinger-Ellison syndrome, and 33% are in patients with MEN1.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

GRFomas are a very uncommon cause of acromegaly but should be suspected in a patient who has acromegaly and abdominal complaints but no pituitary tumor. In addition, it should be considered if a patient has hyperprolactinemia, which occurs in 70% of GRFomas. The intra-abdominal features of GRFomas result from its metastases. The diagnosis is confirmed by performing a plasma assay for GRF and growth hormone.

TREATMENT

The effects of the ectopic growth hormone can be controlled with octreotide (10 to 30 mg intramuscularly every 4 weeks) or lanreotide (90 to 120 mg deep subcutaneous injection monthly) in more than 90% of patients. Treatment also should be directed at the GRFoma per se, as described for the other more common pancreatic neuroendocrine neoplasms. For patients with unresectable advanced disease, treatment is similar to that for other advanced nonresectable pancreatic neuroendocrine neoplasms (outlined later).

NONFUNCTIONAL PANCREATIC NEUROENDOCRINE TUMORS

Nonfunctional pancreatic neuroendocrine neoplasms originate in the pancreas and either secrete no peptides or secrete products that do not cause clinical symptoms. About 50% of all pancreatic neuroendocrine neoplasms are nonfunctional.

Nonfunctional pancreatic neuroendocrine neoplasms frequently secrete nonfunctional peptides, including chromogranin A (100%), pancreatic polypeptide (60%), and the α-subunit (40%) and β-subunit of human chorionic gonadotropin. Immunocytochemically, even higher percentages contain these peptides, as well as insulin (50%), glucagon (30%), and somatostatin (13%).

CLINICAL MANIFESTATIONS

Nonfunctional pancreatic neuroendocrine neoplasms are often found incidentally during investigation of unrelated symptoms or on screening. Symptoms or signs, which result from the neoplasm per se, include abdominal pain (35 to 55%), abdominal mass or hepatosplenomegaly (10 to 40%), weight loss or cachexia (10 to 45%), and jaundice (25 to 40%).

In asymptomatic patients, the incidentally detected nonfunctional pancreatic neuroendocrine neoplasms are usually less than 2 cm, without metastases. In symptomatic patients, primary neoplasms are large (70% were >5 cm) and liver metastases are frequent (38 to 62%).

DIAGNOSIS

Any patients with a long survival (>5 years) after a diagnosis of metastatic pancreatic adenocarcinoma (Chapter 180) should be suspected of having a nonfunctional pancreatic neuroendocrine neoplasm instead. An elevated plasma chromogranin A or pancreatic polypeptide level or a positive somatostatin receptor scintigraphic scan is strong evidence that a pancreatic mass is a pancreatic neuroendocrine neoplasm. Malignancy correlates with vascular/perineural invasion, increased tumor grade, a size of at least 4 cm, capsular penetration, nuclear atypia, lack of progesterone receptors, and the presence of calcitonin immunoreactivity in the neoplasm.[18]

TREATMENT

Surgical resection should be performed, whenever possible, if the nonfunctional pancreatic neuroendocrine neoplasm is greater than 2 to 3 cm, if ductal compression is found, or if a higher grade tumor is present. The role of surgery in nonfunctional pancreatic neuroendocrine neoplasms that are less than 2 to 2.5 cm is controversial, with some experts recommending observation with re-evaluation, whereas others recommended surgery.[19,20] For patients with unresectable advanced disease, treatment is similar to that for other advanced nonresectable nonfunctional pancreatic neuroendocrine neoplasms (see later).

PROGNOSIS

Survival is better in patients with smaller tumors, patients who are asymptomatic at presentation, patients with no metastases, and patients in whom surgical resection can be performed. The overall 5-year survival rate varies in different series from 30% to greater than 90%, but it is heavily dependent on the extent of the disease at diagnosis, with survival rates of 96% in patients without metastases at presentation, but only 30 to 50% with metastatic disease.

ACTHOMAS AND OTHER UNCOMMON TUMORS

Pancreatic neuroendocrine neoplasms that ectopically secrete ACTH cause 4 to 15% of the cases of ectopic Cushing syndrome (Chapter 208).[21] Cushing syndrome occurs in 5% of all cases of Zollinger-Ellison syndrome, but it is a late feature in patients with sporadic Zollinger-Ellison syndrome, in whom it occurs with metastatic liver disease. Its development is associated with a poor prognosis, and the response to chemotherapy is generally poor. However, some patients benefit from the use of long-acting somatostatin analogues (octreotide 10 to 30 mg intramuscularly every 4 weeks) or lanreotide (90 to 120 mg deep subcutaneous injection monthly).

Paraneoplastic hypercalcemia (Chapters 164 and 227) can result from a pancreatic neuroendocrine neoplasm that releases parathormone-related peptide (PTHrP), 1,25 dihydroxy vitamin D, calcitriol, or an unknown hypercalcemic substance.[22] These neoplasms are generally large, with metastatic liver disease at diagnosis. Somatostatin analogues may help control the hypercalcemia, but surgery, chemotherapy, peptide receptor radionuclide therapy, hepatic embolization, and chemoembolization are the mainstays of treatment.

Pancreatic neuroendocrine neoplasms that cause the carcinoid syndrome (see later) are usually large, and 70 to 90% are malignant.[23] Long-acting somatostatin analogues (e.g., octreotide [10 to 30 mg intramuscularly every 4 weeks] or lanreotide [90 to 120 mg deep subcutaneous injection monthly]) may control the symptoms, and the tryptophan hydrolase 1 inhibitor, telotristat (250 mg orally three times daily), may be helpful to control the diarrhea. Surgery, chemotherapy, hepatic embolization, chemoembolization, or molecular targeted therapy (everolimus, sunitinib) may be helpful.

A single case of a pancreatic neuroendocrine neoplasm that secreted renin manifested with severe hypertension; the tumor was localized with somatostatin receptor scintigraphy, and the patient's symptoms improved significantly after resection. A single case of an erythropoietin-secreting pancreatic neuroendocrine neoplasm resulting in polycythemia and a single case of a pancreatic neuroendocrine neoplasm secreting insulin-like growth factor-II or glucagon-like peptide-1 causing hypoglycemia have been described. Two symptomatic cases of pancreatic neuroendocrine neoplasms that secreted luteinizing hormone have been reported; virilization occurred in the female patient, whereas the male patient had increased acne and a rash. In both cases, the tumors were resectable and symptoms improved postoperatively. In a single case of a pancreatic neuroendocrine neoplasm secreting cholecystokinin (CCKoma), the patient demonstrated peptic ulcer disease, gallbladder disease, diarrhea, and weight loss. In one reported case, a pancreatic neuroendocrine neoplasm secreting enteroglucagon caused small intestinal hypertrophy. In one proven case of ectopic secretion of secretin, the patient had achlorhydria and diarrhea with an intestinal fluid high in bicarbonate and chloride.

NEUROENDOCRINE TUMORS OF THE GASTROINTESTINAL TRACT AND THORAX

These well-differentiated neuroendocrine neoplasms, sometimes called carcinoid, occur most often in the gastrointestinal tract (about 25% in the small intestine, 15% in the rectum, 10% in the appendix, and 5% in the stomach) and the lung (30%), but they also can occur in many other organs.

STOMACH NEUROENDOCRINE TUMORS

Gastric neuroendocrine neoplasms occur in several subtypes with differing pathophysiology, natural history, and treatment. Type 1 gastric neuroendocrine neoplasm (carcinoid), which arises in the body and fundus of the stomach in the setting of autoimmune atrophic gastritis, is the most common type, comprising 80% of cases.

In type 1 lesions, gastrin is markedly elevated due to the absence of negative feedback from gastric acid, not because the neoplasms themselves are secreting gastrin. The high gastrin stimulates proliferation of gastric enterochromaffin-like neuroendocrine cells in the body and fundus of the stomach, thereby resulting in hyperplasia of neuroendocrine cells and small multifocal neuroendocrine lesions, which occasionally progress to type 1 gastric carcinoids. These neoplasms are generally of low grade and have a low metastatic potential when less than 2 cm in size and are usually removed endoscopically. Multifocal neoplasms with multiple recurrences can be treated with a somatostatin analogue (e.g., octreotide [10 to 30 mg intramuscularly every 4 weeks] or lanreotide [90 to 120 mg deep subcutaneous injection monthly]) or, very rarely, laparoscopic antrectomy to lower the gastrin level.

Type 2 neuroendocrine neoplasms, which are associated with Zollinger-Ellison syndrome with MEN1, comprise only about 5% of gastric neuroendocrine neoplasms, thereby making them the least common type. These neoplasms are almost invariably multifocal. Unlike type 1 neoplasms, the gastric mucosa is hypertrophic rather than atrophic. The type 2 lesions, which are usually small and of low to intermediate aggressiveness, are best treated with endoscopic excision.

Type 3 neuroendocrine neoplasm is sporadic gastric neoplasm. In comparison to types 1 and 2, type 3 neoplasms are not associated with hypergastrinemia and are usually of higher stage/grade, thereby portending a worse prognosis. These neoplasms can produce an atypical carcinoid syndrome. In most cases, patients require a partial gastrectomy, as for adenocarcinoma of the stomach (Chapter 178).

SMALL BOWEL AND CECAL NEUROENDOCRINE NEOPLASMS

Patients with small bowel and cecal neuroendocrine neoplasms may present with symptoms that are related to the tumor mass or with symptoms caused by biologically active peptides that are released into the circulatory system (e.g., carcinoid syndrome).[24]

Duodenal gastrinomas can be sporadic or can occur in a background of MEN-1, in which they are often associated with Zollinger-Ellison syndrome. In MEN-1–associated cases, hyperplasia of background G cells can be observed. Duodenal somatostatinomas may be associated with psammoma bodies and type 1 neurofibromatosis (Chapter 385). A nonfunctional duodenal neuroendocrine neoplasm can produce calcitonin and serotonin. Ampullary neuroendocrine neoplasms have metastatic potential, even when small, and are also associated with neurofibromatosis.

Most small bowel neuroendocrine neoplasms arise within 60 cm of the ileocecal valve. Approximately 25% of these tumors have multiple primary small bowel foci. Abdominal primary neoplasms or metastases can cause abdominal pain and even intestinal or bowel obstruction owing to growing tumor and associated desmoplasia. A primary tumor may infrequently cause gastrointestinal bleeding. Massive liver metastases can cause palpable hepatomegaly. 5-HIAA, serotonin, chromogranin A, pancreastatin, and neurokinin A are frequently measured biomarkers.

TREATMENT

Localized neoplasms should be treated by resection of the involved segment of small bowel or with right hemicolectomy depending on location. Ampullary tumors are treated with endoscopic resection when possible, although larger, more aggressive tumors, particularly those of the ampulla, may require a modified Whipple resection

PROGNOSIS

The potential for metastasis increases with size, from less than 5% in tumors less than 1 cm to approximately 50% in tumors greater than 2 cm. When metastatic, 5-year overall survival ranges from 40 to 85% and 10-year survival ranges from 40 to 60%.

APPENDICEAL NEUROENDOCRINE NEOPLASMS

Appendiceal neuroendocrine neoplasms are frequently found incidentally at the time of simple appendectomy. If they are less than 2 cm in diameter and have no unfavorable pathologic features, prognosis is outstanding and no additional surgery is needed. However, if these tumors are greater than 2 cm, a right hemicolectomy should be performed.

Mixed neuroendocrine–non-neuroendocrine neoplasms contain both carcinoid elements and elements of adenocarcinoma. These tumors can present as solid masses, as mucinous tumors that can lead to pseudomyxoma peritoneii, or as an adenocarcinoma that overgrows the goblet cell carcinoid. These tumors arise most commonly in the appendix and, because of their aggressive nature, should be treated with a right hemicolectomy, even when less than 2 cm in diameter. These neoplasms must be distinguished from tubular carcinoids, which often have focal mucin present but have an excellent prognosis and are treated as usual appendiceal neuroendocrine neoplasms.

RECTAL NEUROENDOCRINE TUMORS

Hindgut neuroendocrine neoplasms, which arise in the distal colon and rectum, are almost never associated with functional syndromes. Mixed neuroendocrine–non-neuroendocrine neoplasms should be differentiated from high-grade adenocarcinoma of the rectum.[25] Rectal neuroendocrine neoplasms are typically detected on a screening colonoscopy and, if less than 2 cm, can be treated with endoscopic mucosal resection or transrectal excision with low risk of recurrence. However, if the neoplasm is larger than 2 cm or of higher histologic grade, the metastatic risk is greater than 50%, so a low anterior resection of the rectum or anterior posterior resection of the rectum is necessary.

LUNG NEUROENDOCRINE TUMORS

Lung neuroendocrine neoplasms (bronchial carcinoids) comprise 1 to 2% of lung malignancies (Chapter 177) in adults and 20 to 30% of cases of neuroendocrine neoplasms. The annual incidence is 1.35 per 100,000 population per year. About 90% are sporadic, 5% are associated with MEN-1, and occasional cases arise from diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. There is a 5:1 female preponderance without a definite relationship to cigarette smoking

Typical carcinoid has a mitotic count less than 2 per 10 high-power fields and no necrosis. Atypical carcinoid (intermediate grade) has a mitotic count of 2 to 20 per 10 high-power fields and/or focal necrosis. Staging is exactly the same as lung cancer (Chapter 177).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Carcinoid syndrome (see later) with the production of serotonin occurs in less than 10% of cases but can be severe even in the absence of metastatic disease. Histamine-mediated atypical flushing, which persists for more than 30 minutes, is bright red and can involve limbs and upper trunk; it is associated with sweating, tearing, wheezing, burning, and sometimes rosacea. Cushing syndrome from the secretion of ACTH or corticotrophin-releasing hormone (CRH) occurs in less than 5% of patients with lung carcinoid tumors. Acromegaly can occur from ectopic production of growth hormone–releasing factor.

Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, which is characterized by infiltration of lung parenchyma with neuroendocrine cells and tumorlets (<0.5 mm), can lead to the development of multifocal bilateral lung disease. Over many years, it can lead to bronchiectasis, interstitial fibrosis, and bronchiolitis obliterans. CT of the chest, which typically shows numerous subcentimeter pulmonary nodules, should be repeated every 6 months along with pulmonary function tests, including diffusing capacity.

TREATMENT

Surgery is the treatment of choice for localized disease. Endoscopic laser debulking may be helpful to allow for recovery from distal obstructive pneumonia and to allow for a more conservative resection. In the absence of locally advanced disease, sleeve resection often can be performed with minimal loss of functional lung tissue. Video-assisted thoracoscopic surgery (Chapter 87) is recommended to perform lobectomy and lymphadenectomy for accurate staging and to maximize the chance of cure.

The temptation for radical surgery for diffuse idiopathic pulmonary neuroendocrine cell hyperplasia should be avoided to preserve as much lung parenchyma as possible. If the patient becomes symptomatic from progressive disease, somatostatin analogue therapy (e.g., octreotide, 10 to 30 mg intramuscularly every 4 weeks or lanreotide, 90 to 120 mg deep subcutaneous injection monthly) might be considered.

Cushing syndrome can be cured by resection of a localized tumor, but laparoscopic bilateral adrenalectomy is the treatment of choice if it caused by an unresectable or metastatic neuroendocrine neoplasm because medical management is usually inadequate. Acromegaly often responds to somatostatin analogs (e.g., octreotide, 10 to 30 mg intramuscularly every 4 weeks or lanreotide, 90 to 120 mg deep subcutaneous injection monthly) or surgical debulking.

THYMUS NEUROENDOCRINE TUMORS

Thymus neuroendocrine neoplasm is rare, with an annual incidence of 0.02 per 100,000 per year. It accounts for 2% of all mediastinal tumors and 5% of thymic lesions. Most cases are sporadic, but 25% are associated with MEN-1. Functional syndromes, including Cushing syndrome and acromegaly, may occur, as in lung neuroendocrine neoplasms. Criteria for pathologic grade are the same as in lung neuroendocrine neoplasm. There is no accepted staging system, but thymus neuroendocrine neoplasms are usually divided into three groups: encapsulated, invasive, and metastatic. Late presentation with invasion of vital structures is common, but complete resection is the only possible curative procedure. Careful preoperative staging is important. Definitive surgery, which typically requires median sternotomy and mediastinal node dissection and may require cardiopulmonary bypass with cardioplegic arrest, should not be done if significant extrathoracic metastases are present or if the patient is not a good surgical candidate.

CARCINOID SYNDROME

The carcinoid syndrome develops when mediators released by neuroendocrine neoplasms, most commonly metastatic and arising from the small intestine, cause systemic symptoms and signs. The incidence is about 1 to 2 per 100,000 adults. Symptoms include episodic flushing, diarrhea, wheezing, tachycardia, and fluctuations in blood pressure. Patients may eventually develop intraperitoneal and retroperitoneal fibrosis, as well as endomyocardial fibrosis that leads to valvular heart disease. Approximately 8 to 35% of all patients who have neuroendocrine neoplasm develop carcinoid syndrome, most commonly with neoplasms that originate in the small bowel and have metastases to the liver. Foregut (e.g., bronchus, stomach, pancreas, and thymus) and hindgut neuroendocrine neoplasms rarely cause carcinoid syndrome.

Carcinoid syndrome results from the production of biologically active substances, including serotonin, tachykinins, histamine, and prostaglandins that increase blood flow to the skin. Foregut carcinoids frequently produce an atypical carcinoid syndrome due to the release of 5-hydroxytryptophan rather than serotonin.

CLINICAL MANIFESTATIONS

Diarrhea of secretory type is a major feature of the carcinoid syndrome. Stool volume is typically greater than 1 L/day and persists with fasting (when on intravenous fluids). No osmotic gap is present when stool osmolality is measured. Flushing from carcinoid syndrome involves attacks of skin redness, which may be associated with burning and warmth without sweating. Redness is typically noted on the face and neck, sometimes extending to the trunk and abdomen. Psychiatric manifestations of tryptophan deficiency occur when a large percentage of dietary tryptophan is shunted to produce serotonin, thereby leaving less tryptophan to form nicotinic acid and protein. Pellagra (nicotinic acid deficiency; Chapter 199) can be seen when the urinary excretion of 5-HIAA is greater than 100 mg/day as a result of this shunting.

Carcinoid heart disease (Chapter 47) is endomyocardial fibrosis caused by serotonin.[26] The serotonin level is typically greater than 1000 pg/mL, and the urinary 5-HIAA is typically greater than 57 mg/24 hours. Cardiac fibrotic manifestations commonly include tricuspid valve regurgitation (65%), pulmonary valve regurgitation (20%), and right ventricular myocardial restrictive disease, but about 10% of patients may develop left-sided cardiac involvement. Symptoms of right-sided heart failure include swelling in legs and abdomen, shortness of breath, and fatigue. Diagnosis often is easily made by echocardiography.

Intraperitoneal and retroperitoneal fibrosis, which also results from the high level of serotonin, causes intense peritoneal fibrosis that leads to bowel obstruction in about 50% of patients, as well as mesenteric vessel occlusion and bowel ischemia. Retroperitoneal fibrosis can cause ureteral obstruction.

Carcinoid crisis, which is an attack of severe and sustained flushing with life-threatening hemodynamic compromise and bronchoconstriction, is precipitated by anesthesia, surgery, tumor necrosis, or catecholamine infusion. Other manifestations include generalized fatigue, bronchoconstriction, tachycardia, rosacea, and proximal myopathy.

DIAGNOSIS

Carcinoid syndrome should be considered if at least one clinical manifestation is present in patients with a biopsy-proven neuroendocrine neoplasm. The diagnostic hallmark is increased excretion of urinary 5-HIAA. Normally,

urinary excretion of 5-HIAA does not exceed 6 to 10 mg/day when patients have been placed on a low-serotonin diet and have avoided medications that are known to elevate 5-HIAA (e.g., acetaminophen, nicotine, caffeine) falsely before urine collection. Under these circumstances, urinary excretion of 25 mg/day or more of 5-HIAA usually establishes the diagnosis of the carcinoid syndrome. Levels of 9 to 25 mg/day also can be found in patients with vomiting, acute intestinal obstruction, or nontropical sprue. An elevated fasting plasma 5-HIAA level or a platelet 5-HIAA level is an alternative approach.[27] Plasma levels of chromogranin A are frequently elevated in carcinoid syndrome but are not diagnostic.

TREATMENT

Octreotide (subcutaneously every 8 hours, with the dose increased as rapidly as can be tolerated by the patient from 50 to 300 μg three times per day) reduces 5-HIAA excretion by 50% and can dramatically reduce the frequency and intensity of diarrhea and flushing.[A1,28] Once symptoms are improved, the patient can be switched to octreotide LAR, 20 to 30 mg intramuscularly every 4 weeks (or lanreotide 120 mg subcutaneously every month). The addition of telotristat ethyl (250 mg orally twice daily[A2]), which is a potent inhibitor of tryptophan hydroxylase, reduces 5-HIAA by 40%, thereby resulting in marked reduction of diarrhea if it is inadequately controlled by somatostatin analogue therapy alone.

Reducing the bulk of hormone-producing tumor cells by surgery, embolization, or ablation of liver metastasis is also an important component of long-term control of carcinoid syndrome. Systemic therapy with biologic agents such as everolimus, peptide receptor radiotherapy, or interferon may also improve the symptoms of carcinoid syndrome.

For carcinoid heart disease (Chapter 47), diuretics help, but more than 80% of patients die in 4 to 5 years without valve replacement. With replacement of the damaged tricuspid and pulmonic valves, 4-year survival is 50%. Bioprosthetic valves can develop carcinoid fibrosis, but mechanical valves require lifetime anticoagulation, so the choice of therapy must be individualized. Best results for valve replacement occur when the serotonin level is not massively elevated, the patient is younger than 60 years, and heart muscle function is still good (Chapter 60).

PRINCIPLES FOR CONTROLLING GROWTH OF METASTATIC NEUROENDOCRINE TUMORS

Surgery is always an option when either locoregional or metastatic neuroendocrine neoplasm is potentially resectable. Liver-dominant metastasis can potentially be treated with hepatic artery embolization, ablation, or metastasectomy. Metastatic neuroendocrine neoplasms that progress despite a somatostatin analog and that can be detected by somatostatin receptor imaging can be treated with peptide receptor radionuclide therapy. Systemic biologic agents and chemotherapy have a role in managing metastatic disease.

TREATMENT

Primary Debulking Surgery/Regional Therapy/Liver Transplantation

If it is possible to remove at least 90% of metastases surgically,[29] survival as well as symptoms of hormone secretion appear to be improved. Cholecystectomy at the time of abdominal surgery prevents cholelithiasis from somatostatin analogue therapy and makes subsequent liver embolization safer. The primary neoplasm should be removed when carcinoid syndrome is caused by ileal-jejunal neuroendocrine neoplasms to prevent or treat bowel obstruction, bleeding, and other local complications. Liver metastases can be treated with radiofrequency or microwave ablation of lesions less than 4 cm diameter, using a probe inserted into metastasis at surgery or under CT guidance. Irreversible electroporation (NanoKnife), stereotactic radiosurgery, alcohol injection, and other locally destructive techniques can also help to reduce the volume of liver metastases. When liver metastases are too extensive for these techniques, transcatheter hepatic artery embolization can be used. Hepatic artery embolization should be bland embolization or chemoembolization rather than radioembolization, which appears to increase the risk of radiation-induced liver disease when peptide receptor radiotherapy is subsequently used. Liver transplantation is occasionally used for patients who have refractory symptoms with metastatic disease restricted to the liver.

Somatostatin Analogue Therapy

Somatostatin is a peptide hormone that mediates its inhibitory effects on hormone secretion and tumor growth by binding to specific cell-surface G protein–coupled somatostatin receptors. The somatostatin analogs, octreotide and lanreotide, have a longer half-life than somatostatin and bind preferentially to receptor subtype 2, which is the receptor that is most responsible for controlling cell proliferation and secretion, and are effective treatments for controlling symptoms and prolonging survival in pancreatic and gastrointestinal neuroendocrine tumors.[A3]

Peptide Receptor Radionuclide Therapy

Peptide receptor radionuclide therapy uses the binding of a radiolabeled somatostatin analogue to the somatostatin receptor to irradiate selective sites of metastasis with minimal injury to the surrounding normal tissues.[30,31] In patients who become resistant to treatment with maximum approved doses of a somatostatin analogue, such treatment can substantially improve symptoms and progression-free survival.[A4]

Other Therapies

Inhibition of mTOR with everolimus (10 mg orally daily) can increase progression-free survival in patients who have neuroendocrine neoplasms arising from the pancreas, gastrointestinal tract, and lung.[A5] Neuroendocrine tumors are highly vascular and can be controlled with antiangiogenic agents. Sunitinib (an oral tyrosine kinase inhibitor that inhibits VEGFR, PDGFR, KIT, FLT3, and RET at 37.5 mg/day) can prolong progression-free survival in pancreatic neuroendocrine neoplasms. Significant toxicities (seen in <10% of cases) include neutropenia, hypertension, abdominal pain, diarrhea, hypoglycemia, and hand-foot syndrome. Surufatinib (another oral tyrosine kinase inhibitor) also prolongs median survival by about 7.3 months in pancreatic neuroendocrine cancers[A6] and by about 5.5 months in extrapancreatic neuroendocrine cancers.[A7] Cabozantinib and pazopanib are other antiangiogenic agents that have shown promise in neuroendocrine neoplasms and in carcinoid tumors, respectively. Bevacizumab added to everolimus in pancreatic neuroendocrine neoplasms and to octreotide in carcinoid tumors[A8] has improved the response rate but not the progression-free survival, and it currently is not recommended therapy.

For neuroendocrine neoplasms arising outside the pancreas, cytotoxic chemotherapy has a low response rate. For pancreatic neuroendocrine neoplasms, however, treatment under expert guidance can be efficacious. For example, streptozotocin (combined with doxorubicin, cyclophosphamide, or 5-fluorouracil [5-FU]) has response rates reported as high as 70%. The combination of two oral cytotoxic drugs, temozolomide plus capecitabine, appears to have similar activity in pancreatic neuroendocrine neoplasms. For advanced grade neuroendocrine neoplasms, chemotherapy with etoposide and cisplatin, irinotecan plus cisplatin,[A9] or carboplatin has a response rate of 30 to 70%, but it is usually short lasting.[32,33]

214 SEXUAL DEVELOPMENT

PERRIN C. WHITE

DEFINITION

Individuals with differences of sexual development lack concordance of various aspects of gender. These aspects include chromosomal sex (46,XX, 46,XY, or other), gonadal or reproductive sex (ovaries, fallopian tubes, and uterus vs. testes, seminal vesicles, prostate gland, and ejaculatory ducts), genital sex (vagina and clitoris vs. scrotum and penis), and gender-specific behavior.[1-3] Depending on chromosomal sex, most patients can be classified as incompletely masculinized 46,XY males, virilized 46,XX females, and patients with abnormalities of sex chromosomes, such as individuals with mixed gonadal dysgenesis. Many conditions can cause differences of sexual development[4] (Table 214-1).

Normal Sexual Differentiation

Gonadal Differentiation

At 4 to 5 weeks' gestation, the gonadal primordia (gonadal ridges) develop from the coelomic epithelium overlying the medial surface of the mesonephros (primitive kidneys; Fig. 214-1). These primitive gonads are identical in both sexes. Germ cells form at 3 to 4 weeks' gestation and migrate through the gut mesentery into the gonads at this early bipotential stage. This first stage of gonadal development is controlled by homeobox genes.

During the seventh week, XY male gonads begin to differentiate under the influence of testis-determining genes. The first to be expressed is *SRY*, which is the key gene on the Y chromosome that controls male differentiation. Sertoli cells surround germ cells to form testis cords, which nourish primordial germ cells and direct them into the pathway for male gametogenesis. Recruitment of endothelial cells leads to development of a testis-specific vasculature that is required for normal organization of the testis.

Steroidogenic cells develop from the mesonephros and migrate into the developing adrenal cortex and testis at 8 weeks. In the testis, they become Leydig cells, which secrete the testosterone required for subsequent male reproductive development. In the first trimester, testosterone secretion is mainly under the control of human chorionic gonadotropin (HCG), but it subsequently requires luteinizing hormone (LH) secreted by the fetal anterior pituitary.

Ovaries are recognizable at approximately 10 weeks. Ovarian development requires the active participation of several signaling pathways that repress expression of testis-specific genes and promote ovarian development.

Development of Male and Female Internal Reproductive Tracts

The reproductive tracts are derived from intermediate mesoderm. The male reproductive tract develops from the mesonephric (wolffian) ducts, and the female reproductive tract develops from the paramesonephric (müllerian) ducts (Fig. 214-2). Both sets of ducts are present in normal embryos.

Development of wolffian or müllerian structures depends on the presence or absence of normally functioning testes, respectively. The Sertoli cells secrete antimüllerian hormone starting when the testes differentiate.[5] Antimüllerian hormone induces regression of müllerian structures between 8 and 12 weeks' gestation. In its absence, development of the müllerian ducts proceeds, and the female internal structures (fallopian tubes, uterus, cervix, and upper vagina) are formed.

Development of the structures derived from the wolffian ducts, including the epididymis, ductus deferens, ejaculatory ducts, and seminiferous tubules, requires high local concentrations of testosterone secreted from Leydig cells of the testis beginning at approximately 7 weeks' gestation. In the absence of testosterone, wolffian ducts regress. Levels of testosterone in the circulation are insufficient to develop wolffian structures. In conditions in which the gonads develop asymmetrically (e.g., ovotesticular disorders of sexual development or mixed gonadal dysgenesis; see later), wolffian structures develop asymmetrically as well. Development of wolffian structures requires an intact androgen receptor.

Development of the External Genitalia

External genital structures are also bipotential in early gestation and consist of the genital tubercle, genital folds (later, urethral-labial folds), and genital swelling (later, labioscrotal folds) (see Fig. 214-2). Differentiation to male genitalia occurs from approximately 8 to 14 weeks' gestation under the influence of dihydrotestosterone, which must interact with an intact androgen receptor. The genital tubercle becomes the glans penis; the genital folds fuse to become the shaft of the penis and penile urethra, and the labioscrotal folds (derived from the genital swelling) fuse to become the scrotum. Without androgens, these structures become the clitoris, labia minora, and labia majora, respectively.

Normal Gonadal and Adrenal Steroidogenesis

Many forms of genital ambiguity result from defects in steroid biosynthesis in the testes or adrenal cortex or from defective steroid metabolism in the placenta or in target tissues (E-Fig. 214-1). Steroid biosynthesis in the testes and adrenals begins with the importation of cholesterol into mitochondria, a highly regulated process controlled largely by the steroidogenic acute regulatory (StAR) protein. Levels of StAR are controlled within the adrenals by adrenocorticotropic hormone (ACTH) and within the testis by HCG during the first trimester and by LH later in pregnancy.

Within mitochondria, the side chain of cholesterol is cleaved between carbons 20 and 22 by the cholesterol side-chain cleavage enzyme (CYP11A1), which is a cytochrome P-450 enzyme. The product is pregnenolone, which is transported to the endoplasmic reticulum. Some pregnenolone is converted by 17α-hydroxylase (CYP17A1) to 17-hydroxypregnenolone. Both 17-hydroxypregnenolone and the remaining pregnenolone are converted by 3β-hydroxysteroid dehydrogenase (HSD3B2) to 17-hydroxyprogesterone and progesterone, respectively. The side chain of 17-hydroxypregnenolone is cleaved by the 17,20-lyase activity of CYP17A1 to dehydroepiandrosterone (DHEA). DHEA may also be converted to androstenedione by HSD3B2.

All the preceding steps can occur in the adrenal cortex, in Leydig cells of the testis, and (after puberty) in theca cells of ovarian follicles. Subsequent biosynthetic steps are specific to different glands. In the adrenal cortex, 17-hydroxyprogesterone is converted by 21-hydroxylase (CYP21A2) to 11-deoxycortisol, which is then converted in mitochondria to cortisol by 11β-hydroxylase (CYP11B1). Additionally, progesterone is converted to deoxycorticosterone by CYP21A2, which is then converted to aldosterone by aldosterone synthase (CYP11B2).

In Leydig cells of the testis, androstenedione is converted to testosterone by 17-ketosteroid reductase (17β-hydroxysteroid dehydrogenase type 3 [HSD17B3]); the same reaction occurs in theca cells of the ovary, catalyzed by 17β-hydroxysteroid dehydrogenase type 1 (HSD17B1). In granulosa cells of the ovary (after puberty), androstenedione and testosterone are converted by aromatase (CYP19A1) to estrone and estradiol, respectively. In the skin of the developing male external genitalia, steroid 5α-reductase (SRD5A2) converts testosterone to a more potent androgen, 5-dihydrotestosterone.

The placenta is a steroid-synthesizing and steroid-metabolizing tissue as well; it has high steroid sulfatase activity that converts DHEA sulfate from the fetal adrenal gland back to DHEA. DHEA is then successively converted by 3β-hydroxysteroid dehydrogenase type 1 (HSD3B1) and aromatase (CYP19A1) to androstenedione and estrone, respectively, which are then converted to estradiol by HSD17B1.

DIFFERENCES OF SEXUAL DEVELOPMENT

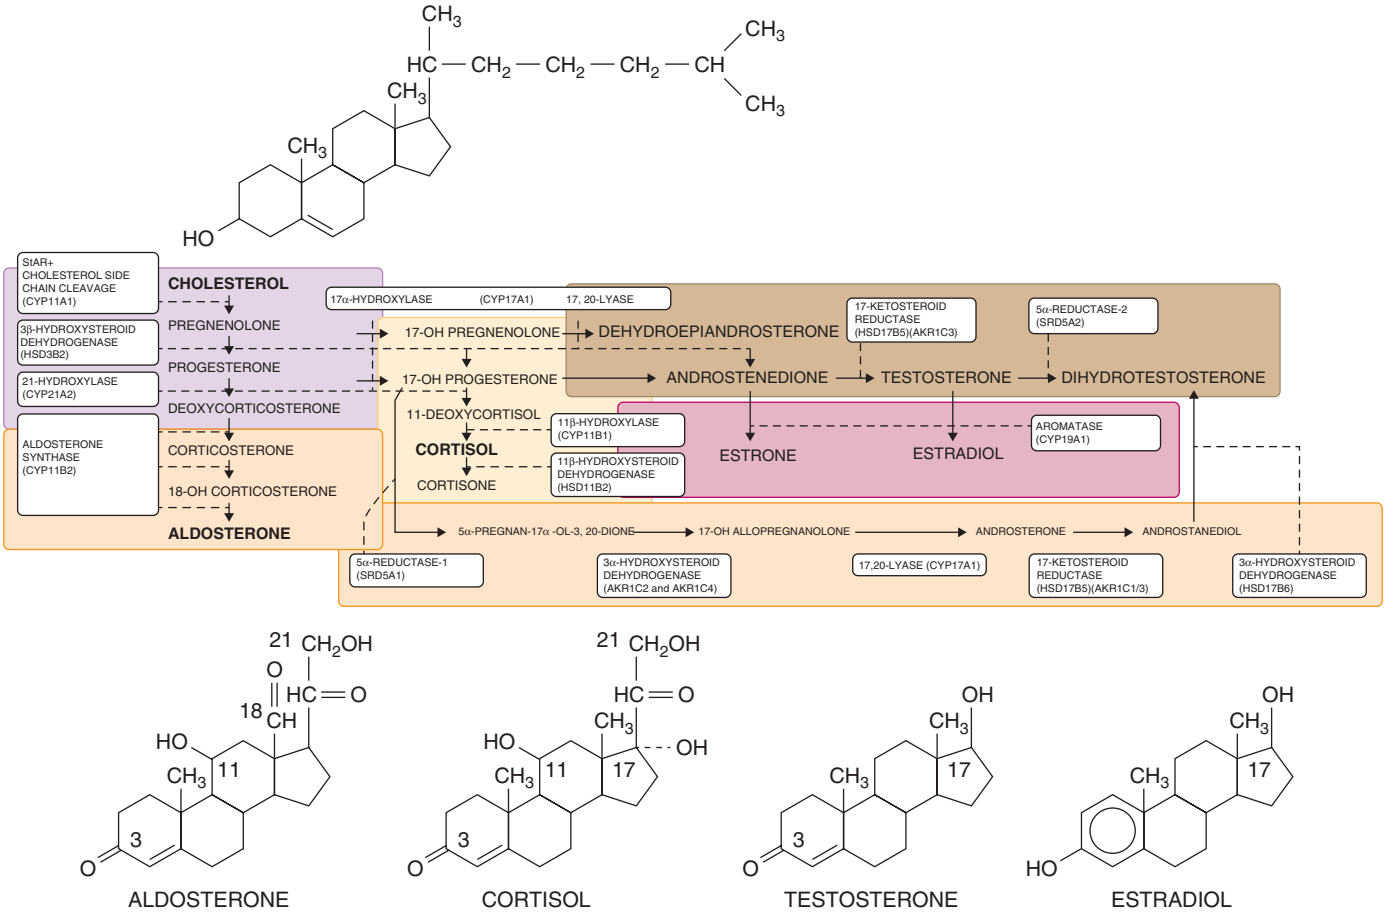
DEFECTS OF STEROIDOGENESIS

Genital ambiguity in genetic females is usually the result of exposure to excessive levels of androgens. Virilizing congenital adrenal hyperplasia, which is the most common cause of genital ambiguity in female infants, occurs in 1 in 16,000 births.

Conversely, severe deficiencies of androgens, if present early in gestation, cause ambiguous or female-appearing external genitalia in male infants. Usually, müllerian structures such as the uterus, cervix, and upper vagina are not present because the testes are able to secrete antimüllerian hormone. Thus individuals with these conditions have a short vagina ending in a blind pouch.

CONGENITAL ADRENAL HYPERPLASIA

The fundamental defect among patients with any form of congenital adrenal hyperplasia is inadequate synthesis of cortisol (see E-Fig. 214-1).[6] Inefficient cortisol synthesis signals the hypothalamus and pituitary to increase corticotropin-releasing hormone and ACTH, respectively (Chapter 204). Consequently, the adrenal glands become hyperplastic, and steroid precursors accumulate proximal to the block in biosynthesis. In some conditions, these precursors can be converted to androgens.



E-FIGURE 214-1. **Adrenal and gonadal steroidogenesis.** Enzymes are boxed with dotted lines extending to arrows denoting each enzymatic conversion; two enzymes, CYP11B2 and CYP17A1, catalyze several successive enzymatic conversions. There are two 11β-hydroxysteroid dehydrogenase isozymes: HSD11B1, which is expressed mainly in the liver, catalyzes reduction (e.g., cortisone to cortisol); and HSD11B2, which is expressed mainly in the kidney, catalyzes oxidation (e.g., cortisol to cortisone). Steps taking place only in the adrenal glands are in unshaded boxes; steps taking place partly or predominantly outside the adrenal cortex are denoted by shaded boxes. Planar structures of cholesterol, aldosterone, cortisol, testosterone, and estradiol are illustrated. Colored rectangles indicate the following: purple, early steps of steroidogenesis common to all zones of the cortex; orange, steps in the zona glomerulosa leading to aldosterone; yellow, steps in the zona fasciculata leading to cortisol; tan; steps in the zona reticularis and testes leading to androgens; orange, the "backdoor" or alternative pathway from 17-OH progesterone to dihydrotestosterone (for clarity, the alternative pathway from progesterone is not shown); magenta, conversions leading to estrogens in the ovary and extragonadal tissues. (Figure adapted from Claahsen-van der Grinten HL, Speiser PW, Ahmed SF, et al. Congenital adrenal hyperplasia—current insights in pathophysiology, diagnostics and management. *Endocr Rev*. 2022;43:91-159.)

ABSTRACT

Individuals with differences of sexual development lack concordance of various aspects of gender, including chromosomal sex (46,XX, 46,XY, or other), gonadal or reproductive sex (ovaries, fallopian tubes, and uterus vs. testes, seminal vesicles, and prostate gland), genital sex (vagina and clitoris vs. scrotum and penis), and gender-specific behavior. Most patients can be classified as incompletely masculinized 46,XY males, virilized 46,XX females, and patients with abnormalities of sex chromosomes, including those with mixed gonadal dysgenesis. Genital ambiguity in genetic females is usually the result of exposure to excessive levels of androgens; congenital adrenal hyperplasia is the most common cause. Conversely, severe androgen deficiencies during early gestation and androgen insensitivity cause ambiguous or female-appearing external genitalia in male infants. Many genetic syndromes interfere with normal gonadal development. Hypogonadotropic hypogonadism of any etiology may result in a micropenis. However, transgender individuals rarely have identifiable hormonal or genetic abnormalities. Children with differences of sexual development should be evaluated with a physical examination, karyotype, and, depending on context, profiles of adrenocortical hormones or sex steroids after stimulation with cosyntropin or human chorionic gonadotropin. Some patients will require gonadal biopsies. A multidisciplinary team should review diagnostic data and make recommendations as to the sex of rearing and any medical or surgical treatments. Depending on the underlying condition, patients may require replacement of pituitary or adrenal hormones and treatment with sex steroids.

TABLE 214-1 DIFFERENCES OF SEXUAL DEVELOPMENT*

VIRILIZATION OR SEX REVERSAL IN XX FEMALES

Virilizing forms of congenital adrenal hyperplasia
- 21-Hydroxylase deficiency (1:16,000 births) [*CYP21A2*]: salt-wasting or simple virilizing forms
- 11β-Hydroxylase deficiency [*CYP11B1*]
- 3β-Hydroxysteroid dehydrogenase deficiency [*HSD3B2*]
- Cytochrome P-450 oxidoreductase deficiency (also has a maternal effect) [*POR*]

Maternal or exogenous androgens
- Drugs (danazol, progestins)
- Luteoma
- Aromatase deficiency [*CYP19A1*]
- Transcription factor mutations
- *AKR1C* genes

Mutations in genes affecting gonadal differentiation
- *SRY* (translocation to X)
- *SOX9* (duplication)
- *SOX3* (duplication)
- *SOX10* (duplication)
- *WT1* (Denys-Drash syndrome)
- *NR5A1*(the Arg92Trp mutation causes ovotesticular difference of sexual development)
- *FOXL2* (ovarian failure associated with blepharophimosis, ptosis, and epicanthus inversus; BPES)
- *RSPO1*
- *WNT4*
- *CBX2*
- *RCA2*
- *ESR2*
- *FSHR*
- *LHX1*
- *NR2F2*
- *NUP107*
- *PSMC3IP*
- *WWOX*

Structural/idiopathic

MICROPENIS

Panhypopituitarism (combined pituitary hormone deficiency) [*PROP1, FGF8, PROKR2, WDR1*]
Septo-optic dysplasia [*HESX1, FGFR1*]
Isolated hypogonadotropic hypogonadism [*GNRH1, GNRHR, KISS1, KISS1R, TAC3, TACR3*]
Other syndromes, including hypogonadotropic hypogonadism
- Kallmann syndrome [*KAL1, AXL, FEZF1, HS6TS1, NSMF, OL14RD, PROK2, SEMA3A, SEMA7A*]
- Prader-Willi syndrome [paternal chromosome 15q11deletion]
- Adrenal hypoplasia congenita [*NR0B1*(*DAX1*)]
- CHARGE complex (colobomata, heart defects, choanal atresia, growth retardation, genital anomalies, ear defects or deafness) [*CHD7*]
- Dandy-Walker syndrome (hypoplasia of the cerebellar vermis and cystic dilation of the fourth ventricle) [*FGF17*]

Lipoid Hyperplasia

Lipoid hyperplasia results from mutations in the *STAR* gene. Cholesterol is not imported efficiently into mitochondria and thus accumulates in cells. Steroid biosynthesis is drastically reduced because of the lack of substrate, and the lipid accumulation quickly kills steroid-synthesizing cells in both the adrenals and the testes. Thus affected male patients are born as phenotypically female because they cannot synthesize testosterone. Affected female patients may undergo transient spontaneous puberty because human ovarian granulosa cells do not synthesize steroid hormones (and thus do not accumulate cholesterol) until puberty. Both sexes have adrenal insufficiency and are unable to synthesize either cortisol or aldosterone. A nearly identical but rare phenotype results from mutations in the *CYP11A1* gene that encodes the cholesterol side-chain cleavage enzyme itself.

17α-Hydroxylase/17,20 Lyase Deficiency

Severe mutations in the *CYP17A1* gene prevent the synthesis of any sex hormones. Affected male patients have female-appearing external genitalia but have no müllerian structures because the testes synthesize antimüllerian hormone. Affected female patients remain sexually infantile without hormone replacement. Milder mutations result in ambiguous genitalia in male patients. Although cortisol synthesis is also abolished, even severely affected individuals are able to synthesize corticosterone, which is an active glucocorticoid, as well as aldosterone, so they do not develop adrenal insufficiency. On the contrary, they secrete excessive amounts of deoxycorticosterone, which has mineralocorticoid activity, and are therefore prone to developing hypertension.

Whereas most *CYP17A1* mutations affect both the hydroxylase and lyase activities, rare mutations can affect the lyase activity alone. Additionally, mutations in an accessory electron transfer protein, cytochrome b_5, or the genes for two aldoketo reductases (*AKR1C2* and *AKR1C4*) can result in the same phenotype as 17,20-lyase deficiency (i.e., deficient androgen synthesis with normal cortisol synthesis).

3β-Hydroxysteroid Dehydrogenase Deficiency

Severe mutations in the *HSD3B2* gene prevent the synthesis of aldosterone, cortisol, testosterone, and estrogens. Because DHEA, a weak androgen, is synthesized and secreted at high levels, some degree of phallic growth is present. Thus affected male patients have severely ambiguous genitalia, but affected female patients may have clitorimegaly. Both sexes develop adrenal insufficiency if they are untreated.

Many children with premature adrenarche (early development of axillary and pubic hair), as well as many women with polycystic ovary syndrome, have elevated levels of DHEA. However, mutations in *HSD3B2* are rarely, if ever, found in such individuals, who instead have an imbalance in the relative levels of HSD3B2 and CYP17 activity within the adrenal cortex.

21-Hydroxylase Deficiency

More than 90% of cases of congenital adrenal hyperplasia are caused by 21-hydroxylase deficiency that results from mutations in the *CYP21A2* gene.[7] *CYP21A2* and a highly homologous pseudogene, *CYP21A1P*, are located within the major histocompatibility complex on chromosome 6p21.3, a genomic region noteworthy for a high rate of recombination. More than 90% of all mutations are the result of intergenic recombination between *CYP21A2* and *CYP21A1P*. Most are transfers of deleterious mutations from *CYP21A1P* to *CYP21A2*, whereas 20% are net deletions of *CYP21A2* resulting from unequal meiotic crossover.

In patients with 21-hydroxylase deficiency, the adrenals produce excess 17-hydroxyprogesterone, 17-hydroxypregnenolone, and progesterone, which are further metabolized to DHEA and androstenedione. Once secreted, these substances are further metabolized to active androgens (testosterone and dihydrotestosterone) and, to a lesser extent, to estrogens (estrone and estradiol). Progesterone and 17-hydroxyprogesterone can also be metabolized to dihydrotestosterone by the alternative "backdoor" pathway (E-Fig 214-1). Additionally, the adrenal gland can synthesize physiologically relevant quantities of 11-hydroxylated and 11-keto-androgens.

Adrenal secretion of excess androgen precursors does not significantly affect male sexual differentiation. In affected female patients, the urogenital sinus is in the process of septation when the fetal adrenal begins to produce excess androgens, which function to prevent the formation of separate vaginal and urethral canals. Further adrenal-derived androgens interact with androgen receptors in genital skin and induce clitoral enlargement, promote fusion of the labial folds, and cause rostral migration of the urethral/vaginal perineal orifice. However, internal wolffian structures such as the prostate gland and spermatic ducts are usually not virilized, presumably because development of the wolffian ducts requires markedly higher local concentrations of testosterone than the external genitalia. Nevertheless, severely affected female patients occasionally have some development of typically male internal genital structures.

Thus the typical result in severely affected girls is ambiguous or male-appearing external genitalia with perineal hypospadias and chordee, but without palpable testes (Fig. 214-3). The severity of virilization is often quantitated using a five-point scale developed by Prader (Fig. 214-4). The degree of genital ambiguity in female patients with classic congenital adrenal hyperplasia is correlated with the severity of enzymatic compromise conferred by each patient's mutations.

FIGURE 214-3. Virilized external genitalia in a female infant with congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. No gonads are present in the scrotum.

Most patients (75%) cannot synthesize sufficient aldosterone to maintain sodium balance and are termed *salt wasters*. These patients are predisposed to episodic and potentially life-threatening hyponatremic dehydration. Patients with sufficient aldosterone production to prevent salt wasting and who have signs of prenatal virilization and/or markedly increased production of hormonal substrates of 21-hydroxylase (e.g., 17-hydroxyprogesterone) are termed *simple virilizers*. A mild nonclassic form occurs in 1/200 to 1/500 individuals and may cause postnatal androgen excess but not prenatal virilization.

11β-Hydroxylase Deficiency

Patients with 11β-hydroxylase deficiency have mutations in the *CYP11B1* gene, with elevated levels of deoxycorticosterone and 11-deoxycortisol, as well as earlier cortisol precursors such as 17-hydroxyprogesterone. These patients secrete excess adrenal androgens, with consequences similar to those seen in 21-hydroxylase deficiency. However, patients with 11β-hydroxylase deficiency synthesize aldosterone normally and do not have problems with salt wasting. Instead, they are likely to become hypertensive as a result of elevated levels of deoxycorticosterone and its metabolites.

DEFECTS OF ANDROGEN BIOSYNTHESIS

Lipoid hyperplasia, 17-hydroxylase/17,20 lyase deficiency, and HSD3B2 deficiency affect the biosynthesis of both corticosteroids and sex hormones. In contrast, two enzymatic defects affect only androgen biosynthesis. They have similar phenotypes. Affected male patients are born with ambiguous genitalia, but they virilize at puberty and often reassign themselves to a male gender if they were raised as females. They have absent müllerian structures as a result of the secretion of antimüllerian hormone by the testes.

17-Ketosteroid Reductase (17-Hydroxysteroid Dehydrogenase 3) Deficiency

This disorder is caused by mutations in the *HSD17B3* gene. Although testosterone is not synthesized well, secretion of androstenedione, an active androgen, is unimpaired. Because several other isozymes have 17-ketosteroid reductase activity in other tissues, some testosterone is invariably synthesized, especially at puberty, when circulating levels of androstenedione increase.

5α-Reductase Deficiency

Patients with 5α-reductase deficiency resulting from mutations in the *SRD5A2* gene synthesize entirely normal amounts of testosterone, but they cannot synthesize adequate amounts of dihydrotestosterone, which is the most potent naturally occurring androgen.[8] This enzyme is not expressed at high levels in the testes (circulating levels of dihydrotestosterone are relatively low); instead, it is expressed in genital skin. Internal wolffian structures do not require this enzyme and are intact; high testosterone levels at puberty induce significant phallic growth without 5α-reductase activity.

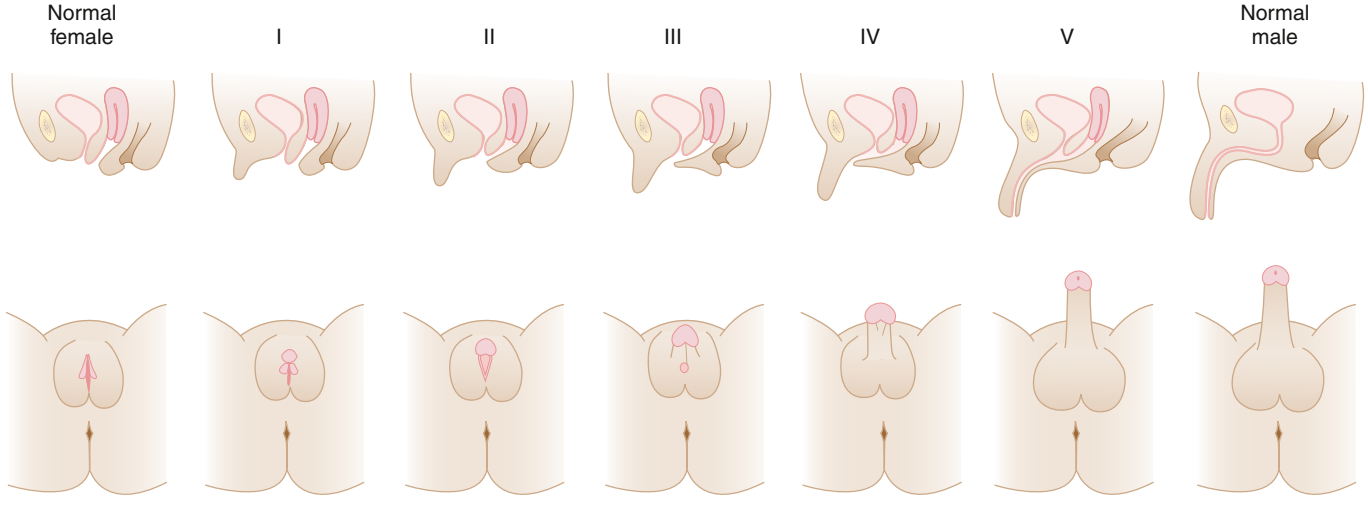

FIGURE 214-4. Abnormal differentiation of the urogenital sinus and external genitalia. Schematic representations of normal female and male anatomy flank a series of schematics illustrating different degrees of virilization of females, graded using the scale developed by Prader. The uterus (*shaded*) persists in virilized females even when the external genitalia have a completely masculine appearance (Prader grade V). (Modified from Prader A. Der Genitalbefund beim Pseudohermaphroditismus femininus der kengenitalen adrenogenitalen Syndroms. *Helv Paediatr Acta*. 1954;9:231-248.)

OTHER DEFECTS OF STEROIDOGENESIS

Aromatase Deficiency

Mutations in *CYP19A1* cause aromatase deficiency in both the fetus and the placenta. The placenta can convert DHEA sulfate to androstenedione and testosterone normally, but it cannot convert these androgens to estrone and estradiol. These androgens accumulate in both the fetal and maternal circulations and virilize both the mother and the affected fetus if it is female. Affected male infants are phenotypically normal. Affected female patients virilize further at puberty if they are untreated. The lack of aromatase activity within bone leads to tall stature in both sexes (because estrogens are required to close the growth plates) and later to osteoporosis.

Cytochrome P-450 Oxidoreductase Deficiency

This deficiency is one form of Antley-Bixler syndrome, which is characterized by skeletal anomalies and craniosynostosis; most patients also have ambiguous genitalia associated with mutations in the *POR* gene.[9] Antley-Bixler syndrome without genital abnormalities is caused by mutations in the FGF receptor (*FGFR2*) gene.

Because this disorder affects the activity of all microsomal cytochrome P-450 subsets, complete deficiency of cytochrome P-450 oxidoreductase (POR) is lethal, and identified mutations in humans yield POR with partial activity. *POR* mutations may cause skeletal anomalies (Antley-Bixler syndrome) by interfering with activity of CYP26B1, an enzyme that degrades retinoic acid. Genital ambiguity is caused by several mechanisms. Decreased activity of 17α-hydroxylase/17,20 lyase (CYP17A1) affects androgen synthesis and leads to undervirilization in males. Conversely, decreased activity of 21-hydroxylase (CYP21A2) can virilize affected females. These two deficiencies also can cause adrenal insufficiency. POR deficiency also diverts steroids into the "back-door pathway" of dihydrotestosterone biosynthesis, thereby contributing to prenatal female virilization. Finally, decreased activity of placental aromatase (CYP19A1) virilizes both the mother and the affected fetus (if female). The extent to which different CYP enzymatic activities are affected depends to some degree on the POR mutations involved.

Smith-Lemli-Opitz Syndrome

This relatively frequent (1 in 20,000 Northern Europeans) disorder of the final step of cholesterol biosynthesis (conversion from 7-dehydrocholesterol) is caused by mutations in the *DHCR7* gene that encodes 7-dehydrocholesterol reductase. The syndrome is characterized by multiple congenital anomalies, including being small for gestational age, short stature, microcephaly, mental retardation, aggressive behavior, seizures, hypotonia, polydactyly, cleft palate, cardiac defects, lung hypoplasia, and renal anomalies. Male patients have ambiguous genitalia. The range of clinical severity is wide and depends on the nature of the mutations.

MATERNAL CONDITIONS AFFECTING THE FETUS

LUTEOMA OF PREGNANCY

Luteomas, which are the most common causes of maternal virilization during pregnancy, often occur bilaterally. Although many luteomas are discovered incidentally during cesarean sections or postpartum tubal ligations, one fourth of mothers virilize during the latter half of pregnancy, and half of female infants born to these mothers also exhibit signs of virilization, most typically clitoromegaly and labial fusion. Spontaneous regression of the luteoma generally begins within days after delivery.

DRUG EXPOSURE

Depending on the agent, maternal drug exposure may affect either male or female fetuses. Females may be virilized by androgens such as 19-nor-testosterone or progestins administered to prevent spontaneous abortion. Undervirilized males can be born to women exposed to 5α-reductase inhibitors such as finasteride. The antifungal agent fluconazole can inhibit many cytochrome P-450 enzymes and can lead to a condition closely resembling Antley-Bixler syndrome.

HORMONE INSENSITIVITY SYNDROMES AND OTHER HORMONE DEFICIENCIES

ANDROGEN INSENSITIVITY

Males normally carry a single copy of the X-linked androgen receptor (*AR*) gene. Thus a single mutation can completely inactivate the receptor in males and lead to complete androgen insensitivity (formerly termed *testicular feminization syndrome*).[10] These mutations, which are among the most frequent forms of 46,XY differences of sex development, occur in approximately 1 in 20,000 male births.

Patients with the complete form of androgen insensitivity have normal female external genitalia. Unless suspicion is raised by prior knowledge of the infant's karyotype, the condition is rarely discovered before puberty unless the testes are palpated in the groin or labia on routine examination. Because the testes secrete antimüllerian hormone, müllerian structures are absent, including the uterus, fallopian tubes, and cervix. Thus the vagina is usually shallow and ends blindly. Wolffian structures are also absent. The testes may be located in the abdomen or in the labia majora and do not undergo spermatogenesis. Levels of antimüllerian hormone are elevated during the first year and (if the testes have not been removed) after puberty. Testosterone and LH levels in infancy and at puberty are elevated as a result of defective feedback regulation caused by androgen resistance at the level of the hypothalamus.

At puberty, pubic and axillary hair is scant or absent. Testosterone can be aromatized to estradiol by CYP19A1 in breast fat, and estrogen receptors are unaffected in this condition. Thus breast development is that of a normal female.

Partial androgen insensitivity (Reifenstein syndrome) is characterized by a variable degree of genital ambiguity, and both virilization and breast development occur at puberty. Mild androgen insensitivity also can occur with a male phenotype, with gynecomastia and infertility as the sole manifestations. Mutations in the androgen receptor are not detected in many mild cases, which may result from defects in other transcription factors affecting actions of the receptor.

LEYDIG CELL AGENESIS

Leydig cell agenesis or hypoplasia is a rare autosomal recessive syndrome caused by mutations in the *LHGCR* gene that encodes the LH receptor. Without stimulation by LH (or by HCG early in gestation), Leydig cells do not differentiate normally and do not secrete testosterone. Thus affected male infants are born with female-appearing or ambiguous external genitalia. Müllerian structures are absent because of unaffected secretion of antimüllerian hormone by Sertoli cells. LH levels are high in infancy and at puberty, and they respond normally to gonadotropin-releasing hormone, whereas testosterone levels are low and do not respond to stimulation by HCG. Affected females are phenotypically normal but may have oligomenorrhea resulting from primary ovarian dysfunction.

PERSISTENT MÜLLERIAN DUCT SYNDROME

Persistent müllerian duct syndrome (PMDS) is a rare autosomal recessive condition that results from mutations in the genes for either antimüllerian hormone (*AMH*, PMDS type I) or the antimüllerian hormone receptor (*AMHR2*, PMDS type II). The two are distinguished clinically by low or absent antimüllerian hormone levels in patients with antimüllerian hormone mutations and by antimüllerian hormone levels in the high-normal range in those with antimüllerian hormone receptor mutations.

Affected male patients have unimpaired testosterone secretion and thus have normal external genitalia and wolffian structures. However, the lack of antimüllerian hormone action prevents regression of müllerian structures, so these patients also retain a uterus and fallopian tubes. These structures are often closely approximated to the vas deferens. The müllerian structures are usually dragged into the inguinal canal by the descending testes. However, these structures typically prevent the testes from descending into the scrotum and thus cause bilateral inguinal hernias (with the uterus on one side) and bilateral or occasionally unilateral cryptorchidism. The condition is usually discovered only at surgery. Fertility in affected patients may be normal or impaired, with an increased risk for malignant disease in undescended testes left in the abdomen.

HYPOGONADOTROPIC HYPOGONADISM

Milder or later-appearing deficiencies of androgen biosynthesis (after 13 to 14 weeks) may allow complete fusion of the labioscrotal folds and normal positioning of the urethral meatus, but subsequent growth of the phallus is suboptimal. Such individuals have a micropenis. The most common cause is lack of gonadotropin (specifically, LH) secretion; even when LH is lacking, early male development is normal because testosterone secretion is controlled mostly by HCG during the first trimester.

Causes of hypogonadotropic hypogonadism are discussed in Chapter 216.

OTHER GENETIC CONDITIONS

ANEUPLOIDY OF SEX CHROMOSOMES

Turner Syndrome

Patients with Turner syndrome have normal female external genitalia and a normal uterus and fallopian tubes, but they have dysgenetic streak ovaries.[11] Most fetuses with Turner syndrome spontaneously abort, but the incidence in live births is approximately 1 in 2500. Classically, the karyotype is 45,X, but many patients retain an abnormal second X chromosome or even a fragment of a Y chromosome lacking *SRY*. Other patients are mosaic for 46,XX and 45,X cells and may have relatively mild phenotypes.

Untreated patients are short. Many have typical dysmorphic features, including lymphedema of the neck at birth, webbed neck, low posterior hairline, increased carrying angle of the arms, shield chest with widely spaced nipples, low-set ears, and micrognathia. Patients typically have primary amenorrhea and are infertile, but they occasionally have menarche followed by premature ovarian failure. Estrogen therapy can significantly improve bone density,[A1] but it is unclear whether it reduces fractures or improves long-term outcome.[12]

Klinefelter Syndrome

In this condition, male patients have normal development of the penis and scrotum, but the testes are small and firm. Patients tend to be tall. At adolescence, gynecomastia is frequent.[13] Signs of testosterone deficiency occur in most affected adults, and most have azoospermia. The usual karyotype is 47,XXY. Hormonal findings include elevated gonadotropin levels and a decreased serum testosterone concentration. Klinefelter syndrome is a common disorder that occurs in 1 in 500 to 1000 men.[14]

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis, which is a frequent cause of sexual ambiguity, occurs in approximately 1 in 20,000 births. The karyotype is usually mosaic 45,X/46,XY. Gonadal pathologic features can vary from fibrous streaks indistinguishable from those in Turner syndrome to normally developed testes and a normal male phenotype. Typically, patients have a testis on one side and a fibrous streak on the other. Some patients may have a Turner-like phenotype. A fallopian tube is usually present on the side of the streak gonad. Leydig cell function, evaluated by testosterone response to HCG, and Sertoli cell function, evaluated by serum antimüllerian hormone levels, vary from poor to normal.

XX MALE SYNDROME

Males with a 46,XX karyotype have normal external and internal male genitalia, but they resemble patients with Klinefelter syndrome in that they have small testes, azoospermia, and infertility. Translocation of the *SRY* gene to the X chromosome is detected in 75 to 90% of sporadic cases. This translocation can occur because the gene is located very near the pseudoautosomal region, where the short arms of the X and Y chromosomes are homologous and meiotic recombination is possible. Duplication of the *SOX9* transcription factor gene may be responsible for some familial cases of XX sex reversal.

XY FEMALE SYNDROMES

Patients with pure XY gonadal dysgenesis (Swyer syndrome) have a normal female phenotype, including a uterus and fallopian tubes, but they have streak gonads. These patients are free of Turner-like malformations and attain normal height. Mutations of the *SRY* gene have been identified in 15% of cases. Unlike 45,X patients with Turner syndrome, these patients have an increased risk for gonadoblastoma.

Similar phenotypes result from duplication of the region of the X chromosome containing the *NR0B1* (*DAX1*) gene, from duplication of the *WNT4* gene, or from haploinsufficiency of the *NR5A1* (SF1) transcription factor.[15] XY sex reversal also can result from mutations in the *SOX9* transcription factor gene associated with campomelic dysplasia, which is a form of dwarfism. Mutations of *DHH* cause XY gonadal dysgenesis associated with peripheral neuropathy.

Frasier and Denys-Drash syndromes are rare, phenotypically overlapping diseases caused by inherited or de novo mutations in *WT1*. They are both characterized by XY gonadal dysgenesis and an increased risk for gonadal tumors. Progressive glomerulopathy developing in early childhood is associated with both syndromes, but Denys-Drash patients demonstrate diffuse mesangial sclerosis, whereas Frasier patients develop focal and segmental glomerulosclerosis (FSGS).[16]

Some 46,XY patients with absent gonads have various degrees of sexual ambiguity and no müllerian derivatives. The implication that some testicular tissue was functional at least up to 10 weeks' gestation and subsequently regressed led to the name *fetal testicular regression syndrome*.[17] Testicular regression may occur in late pregnancy or even postnatally. These fully virilized male patients have isolated anorchia.

VAGINAL ATRESIA

Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, which refers to aplasia of the uterus and upper vagina, occurs in approximately 1 in 5000 women.[18] In approximately one third of cases, it occurs along with other abnormalities, including unilateral renal aplasia and cervicothoracic somite dysplasia (type II MRKH; MURCS association). The genetic basis is unknown in most cases. Rare affected individuals have heterozygous mutations of *WNT4;* such patients usually have clinical and biochemical signs of androgen excess.

OVOTESTICULAR DISORDER OF SEXUAL DEVELOPMENT (TRUE HERMAPHRODITISM)

Ovotesticular disorder of sexual development (true hermaphroditism), which is a rare and usually sporadic disorder, is defined as the coexistence of seminiferous tubules and ovarian follicles. Most patients have an ovotestis with either an ovary or a testis on the opposite side; a gonad in the scrotum is usually a testis but may be an ovotestis.

The genitalia are usually ambiguous, but they may appear completely masculine or feminine. The anatomy of the internal reproductive tract depends on the nature of the gonads, particularly whether they secrete antimüllerian hormone. A uterus or uterine horn is present in 90% of cases. Testosterone response to HCG is variable, and antimüllerian hormone levels are usually low. Most patients experience breast development, ovulation, and even menstruation at puberty; pregnancy and successful childbirth are possible if selective removal of testicular tissue is feasible. Unless sex of rearing has already been chosen, male gender assignment should be restricted to patients with no uterus and descended testicular tissue because the latter is usually dysgenetic and prone to malignant degeneration. Most patients with ovotesticular disorder of sexual development have a 46,XX karyotype. Despite the presence of testicular tissue, they usually lack *SRY*. Some patients in different ethnic groups and locales carry a specific mutation in *NR5A1*, Arg92Trp.

MANAGEMENT OF INDIVIDUALS WITH DIFFERENCES OF SEXUAL DEVELOPMENT: GENDER ROLE AND IDENTITY

The influence of prenatal sex steroid exposure on personality is controversial.[19] In considering this question, it is important to distinguish among gender role, sexual orientation, and gender identity.

GENDER ROLE

Gender role refers to gender-stereotyped behaviors, such as the choice of toys by young children. For example, parents of young girls with congenital adrenal hyperplasia often report that their daughters prefer to play with trucks rather than dolls and tend to be tomboyish later in childhood. Decreased interest in maternal behavior, beginning with infrequent doll play in early childhood and extending to lack of interest in child rearing in older girls and women, occurs frequently.

SEXUAL ORIENTATION

Sexual orientation refers to homosexual versus heterosexual preferences. In many studies, a significant minority of women with congenital adrenal hyperplasia have been actively homosexual or bisexual or have had an increased tendency toward homoerotic fantasies. These characteristics occur more frequently in women with the salt-wasting form of 21-hydroxylase deficiency, thereby suggesting that they are a consequence of prenatal exposure of the brain to androgens. However, the vast majority of both male and female homosexuals have no identifiable endocrinologic abnormality.

GENDER IDENTITY

Gender identity refers to self-identification as male or female. Gender self-reassignment back to male has been reported in cases of male patients with penile trauma or exstrophy of the bladder who were raised as girls.

Gender self-reassignment also occurs in some 46,XY patients who have differences of sexual development and who were raised as girls, especially in cases of 5α-reductase or 17-ketosteroid reductase deficiencies, in which the fetal brain may be exposed to high circulating levels of androgens. The rate of gender change from female to male in persons with 5α-reductase deficiency ranges from about 15 to 70% in different countries, and the rate of gender changes in persons with 17-ketosteroid reductase deficiency is about 50%.

Self-reassignment to the male gender is unusual in women with congenital adrenal hyperplasia, with 4% reporting gender dysphoria, usually related to delays in gender assignment or genital surgery or to inadequate suppression of adrenal androgens with glucocorticoid therapy. Conversely, a significantly higher proportion (15%) of female patients who have congenital adrenal hyperplasia and who are raised as males experience gender dysphoria. The prevalence of gender identity disorder in patients with complete androgen insensitivity raised as females is extremely low (less than 2%), but it is much higher (12 to 25%) in patients with partial androgen insensitivity, whether they are raised as males or females.[20]

Transgender individuals (see Chapter 215) rarely have identifiable hormonal abnormalities, and the nonhormonal mechanisms governing gender identity are poorly understood. Gender identity disorders are much more likely to occur in both identical twins than in fraternal twins, thereby suggesting a high degree of heritability. Neuroanatomic studies suggest that the bed nucleus of the stria terminalis is larger in males and trans males (female-to-male transsexuals) and smaller in females and trans females (male-to-female transsexuals). Similar findings involving other sexually dimorphic brain regions have been identified by magnetic resonance imaging.[21] Thus gender identity disorder may be considered a brain-limited difference of sexual development.

DIAGNOSIS

Management of a child born with ambiguous genitalia presents a difficult challenge to medical personnel. It is important to refrain from assigning sex until diagnostic information can be gathered. Usually, test results can be obtained within 24 to 48 hours, and parents can be advised about the child's chromosomal and gonadal sex and the anatomy of internal sexual structures.

In addition, the physician must keep in mind that differences of sexual development may be associated with life-threatening biochemical or anatomic abnormalities. In particular, the most common cause of severely masculinized external genitalia in females, the salt-wasting form of congenital adrenal hyperplasia resulting from steroid 21-hydroxylase deficiency, may cause hyponatremia, hyperkalemia, hypovolemia, and shock. In contrast, male patients with ambiguous genitalia may have lipoid adrenal hyperplasia or a salt-wasting form of 3β-hydroxysteroid dehydrogenase (HSD3B2) deficiency. Males with micropenis may have panhypopituitarism; in this case they are at risk for significant hypoglycemia and hyponatremia resulting from low cortisol (because of low ACTH) and low growth hormone levels, or they may have adrenal hypoplasia congenita, in which case they could have adrenal insufficiency. Finally, patients with ambiguous genitalia are at increased risk for renal anomalies, or they may have chromosomal syndromes with other associated anomalies.

History

The gestational history should concentrate on potential exposure to agents that could interfere with normal sexual differentiation (e.g., exposure of a female infant with virilized genitalia to progestational agents or the mother of a male with incompletely masculinized genitalia to 5α-reductase inhibitors). A family history should elicit similar cases of genital ambiguity or cases of sudden infant death, which could raise suspicion of undiagnosed salt-wasting congenital adrenal hyperplasia or adrenal hypoplasia congenita.

Physical Examination

The physical examination should document the size of the phallus (clitoris or penis), the degree of chordee (ventral bowing of the phallus), and the extent of fusion of the labioscrotal folds. The urethral meatus should be identified, and careful palpation should search for gonads in the inguinal canals, labia, or scrotum. Bilateral cryptorchidism, even if an isolated finding in a phenotypic male patient, should always lead to evaluation for a possible difference of sex development.

Biochemical Evaluation of the Virilized Female

The minimal diagnostic tests should include measurement of basal serum levels of 17-hydroxyprogesterone, androstenedione, and testosterone. Preferably, a complete profile of adrenocortical hormones is obtained before and 1 hour after stimulation of the adrenal cortex with 125 to 250 μg of cosyntropin ($ACTH_{1-24}$). These assays, which should be deferred until after the first 24 hours of life, will identify potential defects in adrenal steroidogenesis (i.e., congenital adrenal hyperplasia): 21-hydroxylase deficiency is identified by elevations in 17-hydroxyprogesterone, whereas 11-deoxycortisol and 11-deoxycorticosterone are high in 11β-hydroxylase deficiency.

Biochemical Evaluation of the Undervirilized Male

In 46,XY patients with differences of sexual development, adrenal and gonadal function, as well as extragonadal androgen metabolism, must be tested. With regard to adrenal defects, 11-deoxycorticosterone and the ratio of pregnenolone to 17-hydroxypregnenolone are high in 17α-hydroxylase deficiency, 17-hydroxypregnenolone and DHEA are high in HSD3B2 deficiency, and all steroids are low in lipoid hyperplasia.

Defects in gonadal steroidogenesis are best evaluated after stimulation with HCG (1500 IU intramuscularly on days 1, 3, and 5, with blood drawn on day 6). However, 17-hydroxylase and HSD3B2 deficiencies affect both the gonads and the adrenal cortex and thus are often diagnosed by cosyntropin stimulation testing. Low levels of all androgen precursors suggest lipoid hyperplasia, 17α-hydroxylase/17,20-lyase deficiency, or a generalized defect in testicular function, such as the vanishing testes syndrome (testicular regression syndrome) or gonadotropin insensitivity. A high ratio of androstenedione to testosterone is indicative of 17-ketosteroid reductase (HSD17B3) deficiency, and a high ratio of testosterone to dihydrotestosterone is diagnostic of 5α-reductase deficiency. The diagnosis of androgen insensitivity syndrome is suspected when a 46,XY patient has ambiguous or female-appearing external genitalia despite normal or high circulating levels of testosterone and dihydrotestosterone.

Genetic Evaluation

Genetic evaluation of a patient with a possible difference of sex development almost always begins with a karyotype to count sex chromosomes, assess the degree of mosaicism, and determine chromosomal abnormalities such as translocations. If time is pressing, fluorescent in situ hybridization on metaphase nuclei may provide a count of sex chromosomes within less than a day. Next-generation sequencing may be useful in patients in whom the etiology is uncertain.

Gonadal Biopsies

Patients with mixed gonadal dysgenesis, ovotesticular disorders of sexual development, or unclear diagnoses should undergo bilateral gonadal biopsies (histology of the two gonads is often not identical). Dysgenetic gonads have a high potential for malignant transformation and usually need to be removed in childhood.

TREATMENT

Initial Medical Management

Patients with congenital adrenal hyperplasia resulting from 21-hydroxylase or HSD3B2 deficiencies and patients with lipoid hyperplasia or adrenal hypoplasia congenita require replacement of both glucocorticoids and mineralocorticoids, usually with hydrocortisone (10 to 15 mg/m^2/day in divided doses) and fludrocortisone (usually 0.1 mg/day, but as much as 0.4 mg/day in neonates with salt-wasting crises). Neonates with severe salt losses may require sodium chloride supplementation (≤8 mEq/kg/day). Patients with 11β-hydroxylase or 17α-hydroxylase deficiencies have normal aldosterone biosynthesis and usually require only glucocorticoids. Patients with panhypopituitarism usually require treatment with hydrocortisone, thyroxine, and growth hormone.

All male infants with ambiguous genitalia or micropenis in whom rearing as a boy is contemplated should have a 3- or 4-month therapeutic trial of monthly depot testosterone injections (25 mg) to attempt to increase the size of the phallus during infancy. This treatment may improve social acceptability of the genitalia later in childhood and adolescence and may make reconstructive surgery easier. In cases of suspected partial androgen insensitivity, this treatment also documents the degree to which the patient is androgen responsive and thus may provide useful information about whether rearing as a boy is feasible. Higher doses of testosterone (75 mg every 4 weeks) may be used under these circumstances.

Considerations Related to Sex Assignment

In large medical centers, a multidisciplinary team consisting of a neonatologist, a pediatric endocrinologist, a urologist, and preferably an experienced social worker and/or child psychiatrist or psychologist should promptly review the early diagnostic data and make a recommendation to the family as to the sex of rearing and any medical or surgical treatments. These recommendations should be based on both current knowledge of psychosexual development in individuals with differences of sex development and the feasibility of surgical treatment (see later).

In general, the recommended sex assignment should be that of the genetic/gonadal sex, if for no other reason than to retain the possibility of reproductive function. This approach is especially recommended for female infants with congenital adrenal hyperplasia who have normal internal genital structures and the potential for childbearing. An exception may be considered in a genetically female infant with completely male-appearing genitalia, especially if the child has been raised as a boy for more than a few months. Such children need to be castrated at puberty to avoid feminization.

Conversely, genetic male infants with completely female-appearing external genitalia (usually resulting from complete androgen insensitivity syndrome, but also seen with severe testosterone biosynthetic defects) should be raised as female because the potential for reconstruction of male genitalia is poor. However, male infants with 17-ketosteroid reductase or 5α-reductase deficiency should usually be reared as boys because they have normal levels of androstenedione or testosterone, respectively, and they often virilize significantly at puberty. Indeed, as noted previously, many of these patients reassign themselves to the male gender when they are made aware of the diagnosis. The same considerations pertain to male patients who have normal testosterone biosynthesis but who have penile trauma or anatomic abnormalities such as bladder exstrophy.

Surgical Management

Surgery for Ambiguous Genitalia

Whether, how, and when to intervene surgically in the treatment of genital anomalies are the subject of continuing debate.[22] Some adult patients with differences of sexual development are unhappy with their gender assignments or surgical outcomes. Some physicians advocate postponing cosmetic genital surgery until the affected individual is able to provide informed consent, thereby keeping all the options open if the adult patient wishes to function sexually with abnormal genitalia that nevertheless have sensation undiminished by surgery or if the patient chooses to reassign their gender. The option of deferring surgery should always be presented as part of the informed consent process.

The greatest change in practice over the past few decades probably pertains to male infants with ambiguous (but not completely female) external genitalia. Physicians are far less likely to recommend that such patients be reared as female because it is now recognized that many of these patients reassign themselves as male at puberty. Thus the ambiguous genitalia in such patients should rarely be "corrected" to female. On the contrary, surgical techniques to repair hypospadias have advanced significantly, and reconstruction of male genitalia is attempted more often, particularly if the infant responds to a course of testosterone with significant phallic growth.

Surgery for female infants with ambiguous genitalia may need to address an enlarged clitoris, the lack of a vaginal introitus, and the presence of a urogenital sinus. The clitoris is normally prominent in many infant girls. Even when enlarged in a girl with virilizing congenital adrenal hyperplasia, the clitoris can be prevented from growing larger with adequate suppression of adrenal androgens by glucocorticoids, and it will become less prominent as the patient grows. Thus mild-to-moderate clitorimegaly is often best managed without surgery. When clitoroplasty is attempted, one must keep in mind the important role of clitoral sensation in the female sexual response. Such surgery must be performed only by experienced operators with scrupulous attention to the preservation of clitoral innervation.

Consensus is lacking regarding the best age for vaginoplasty.[23] Although many surgeons advocate a first procedure in infancy, it is difficult to maintain a functionally adequate introitus in the absence of estrogen exposure and mechanical dilation (with dilators or through sexual intercourse), and many patients require reoperation as young adults. Conversely, many women with atresia of the upper vagina (owing to complete androgen insensitivity or the Mayer-Rokitansky-Küster-Hauser syndrome) can use dilators to lengthen the vagina without the need for surgery.[24] According to self-assessment surveys among sexually active women with congenital adrenal hyperplasia who have had genital surgery, most are able to have satisfactory sexual intercourse. As surgical and medical treatment regimens have improved in recent years, more women with congenital adrenal hyperplasia have successfully conceived spontaneously, completed pregnancies, and given birth.

Repair of hypospadias is usually begun in the first year of life, after testosterone treatment (if necessary to increase phallic size). Depending on the degree of hypospadias, more than one surgical procedure may be required.

Removal of Intra-abdominal Testes in 46,XY Patients with Differences of Sexual Development

Intra-abdominal testes are at increasing risk for malignant transformation over time. In a boy who has cryptorchidism and who is being reared as male, orchiopexy should be performed as quickly as possible to maximize the possibility of fertility if the underlying condition does not preclude it. Dysgenetic gonads that cannot be brought into the scrotum should be removed soon after diagnosis because the risk for malignant transformation in childhood is relatively high.

There is a lack of consensus regarding nondysgenetic testes in severely undervirilized genetic male infants in whom rearing as female is planned. In patients with complete androgen insensitivity or complete defects in testosterone biosynthesis, no possibility of fertility exists, and so there seems to be no reason to retain the testes. Conversely, the risk for malignant transformation in such gonads is low before puberty, and patients with complete androgen insensitivity can undergo spontaneous breast development at puberty. At that time, patients themselves can assent or consent to gonadectomy, which can usually be accomplished laparoscopically. This approach is of particular importance in genetic male patients with partial androgen insensitivity or incomplete defects of testosterone biosynthesis, because such patients may eventually desire a male gender role.

Patients with persistent müllerian duct syndrome have a reduced but still appreciable potential for fertility, and virilization is unaffected. Thus the testes should be removed only if they cannot be brought into the scrotum. Because the müllerian and wolffian structures are closely approximated in these patients, surgical excision of the uterus and fallopian tubes may result in ischemic and/or traumatic damage to the vas deferens and testes; thus salpingectomy and hysterectomy are indicated only in patients whose müllerian structures limit intrascrotal placement of the testes.

Treatment of vaginal agenesis in adolescent or adult women with the Mayer-Rokitansky-Küster-Hauser syndrome may include noninvasive vaginal dilations as first-line therapy or surgery. Until recently, the only option for the patients to achieve biological motherhood was through gestational surrogacy, but successful uterine transplantation has been reported.

Management of transgender adults is discussed in Chapter 215.

Psychosocial Support

Families of patients with differences of sex development should be assessed for emotional health, initially by the pediatrician and/or pediatric endocrinologist. Parents should be offered psychological counseling soon after the diagnosis is made. Intermittent assessment of family functioning may be a useful tool in predicting future problems. As children mature, they should repeatedly be informed about their condition by parents and physicians in a sensitive and age-appropriate manner. When psychotherapy is undertaken, medical and psychiatric caregivers should communicate with each other and with experts in sexual development so all are working together.

Although the psychosexual development of individuals with differences of sex development cannot be predicted with confidence, patients' families should receive anticipatory counseling. For example, counseling of parents of girls affected with congenital adrenal hyperplasia should address the high likelihood that such girls will exhibit tomboyish behavior and masculine play preferences. The endocrinologist and/or mental health professional (depending on inclination and experience) caring for adolescents with differences of sexual development should address sexual orientation, both fantasized and actual. For example, some women with congenital adrenal hyperplasia are homosexuals; such individuals should receive appropriate psychosocial support. Adult patients also should be made aware of relevant patient advocacy groups.

215 TRANSGENDER MEDICINE

JOSHUA D. SAFER

DEFINITION AND EPIDEMIOLOGY

Gender identity is the internal sense of one's own sex, whether male, female, neither, both, or something else. Transgender is a broad term to reference individuals with gender identity that differs from sex recorded at birth, typically based on external genitalia (Table 215-1). In the United States, an estimated 0.6% of adults, or approximately 1.4 million individuals, are transgender.[1] Cisgender describes individuals with gender identity that aligns with recorded sex at birth. Other terms with similar meaning to transgender include trans, gender incongruent, gender nonbinary, gender diverse, and genderqueer—all terms being adjectives for people with gender identity that is not aligned with visible anatomy at birth. The latter three terms reference people who are less binary in their sense of their sex identity. The term transsexual is an older word that previously referenced transgender individuals who had "completed" planned treatment to change their bodies to better align with their gender identities.[2]

PATHOBIOLOGY

Historically, being transgender was considered a mental health problem with a mental health solution. Indeed, the term gender dysphoria has been used for a transgender person whose gender identity is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.[3] However, not every transgender or gender-diverse individual experiences dysphoria, including transgender people seeking medical treatment. Further, some transgender people will suffer clinical dysphoria independent of their being transgender. In the former case, a transgender person might be treated with gender-affirming hormones or surgeries. In the latter case, a person may need mental health approaches to the clinical dysphoria independent of any need for gender-affirming medical intervention. Thus, the *International Classification of Diseases*, 11th edition removes the term *gender dysphoria* entirely and adds the term *gender incongruence* to a new sexual health section.[4]

The current model is that gender identity is a biologic phenomenon that cannot be influenced externally. Data for the biologic underpinnings to gender identity include evidence from studies of people who are intersex or have differences of sexual differentiation, evidence from twin studies, evidence from studies of the impact of prenatal androgen exposure, and evidence from studies of certain neurologic structures. For example, among XY children with cloacal exstrophy (Chapter 214), with or without penile agenesis and penile ablation, who are assigned female at birth, a substantial proportion are not comfortable with that designation.

When one identical twin is transgender, the other will also be transgender 40% of the time. By comparison the concordance rate among fraternal twins is zero or close to zero.

For XX chromosome individuals with virilizing congenital adrenal hyperplasia (Chapter 214), male gender identity may be present in 5%, nearly 10-fold the rate of male gender identity among XX chromosome people in general. Among XY individuals with complete androgen insensitivity syndrome, nearly all have female gender identity. The implication is that some androgen action on the brain may be necessary for male gender identity and that increased in utero androgen exposure may confer male gender identity in some individuals. Even if some minimal androgen action on the brain proves necessary for male gender identity, it is not sufficient. There is no evidence that most transgender people have either excess or deficient exposure to androgens.

Studies of the brains of transgender individuals suggest a physical manifestation associated with gender identity. A postmortem study of six transgender women (male-to-female) found that the size of the bed nucleus of the stria terminalis in the hypothalamus was within the female range independent of historical hormone treatment. Brain imaging studies suggest that hormonally untreated transgender men exhibit white matter microstructure more typically male than female and that untreated transgender women exhibit white matter microstructure intermediate between cisgender male and cisgender female individuals.

TABLE 215-1 DEFINITION OF GENDER TERMS

Sex/Gender: Umbrella terms to reference biologic characteristics, identification, and stereotypical behaviors that are considered male, female, or some variation. The word gender is sometimes used as a synonym for the word sex in colloquial use and is also sometimes used as shorthand for either gender identity or gender expression.
Gender Identity: Internal sense of one's own sex as male, female, both, or neither.
Gender Expression: How an individual communicates gender identity to themselves and others.
Transgender, Transsexual, Trans, Gender Diverse, Gender Nonbinary, Gender Incongruent,* Genderqueer: Adjectives for individuals with a gender identity that is not aligned with sex recorded at birth.
Cisgender, Nontransgender: Adjectives for individuals with a gender identity that is aligned with sex recorded at birth.
Gender-Affirming/Gender-Confirming Hormone Treatment and Surgeries: Medical interventions for transgender and gender-diverse individuals to align gender identity better with other physical characteristics.
Intersex: A term for people with sexual and/or reproductive anatomy that is not typical (may also be labeled people with differences of sexual differentiation).

*This term is replacing the term gender dysphoria to label the lack of alignment for some individuals between their gender identity and their sex as recorded at birth.

Adapted from Safer JD, Tangpricha V. Care of transgender persons. *N Engl J Med.* 2019;381:2451-2460.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Children may articulate gender identity as early as age 2 years and proceed to demonstrate facility with gender labeling, including their use of pronouns, by school age. About 0.6% to 2.7% of children may report some degree of gender diversity.[5] By adolescence, many children clearly articulate gender identity, such that adolescents who present as transgender people seeking gender-affirming treatment are overwhelmingly stable in their reported gender identity into adulthood. Puberty can be distressing for transgender children, with the "wrong puberty" serving as the trigger for some adolescents to report their gender identity to their parents and health care providers.

Most transgender persons present for gender-affirming medical intervention as older adolescents or adults, perhaps because of factors such as late recognition of gender identity, failure to articulate gender identity, or outside pressure to conform. Despite the older presentation, most transgender people report that, in retrospect, they were aware of their gender incongruence before puberty.

Transgender people present in heterogenous fashion.[6] Some transgender people are confident in their sense of their gender identity and their treatment goals. Others may benefit from greater support from mental health providers, either to help articulate gender identity or to help with goals.

Clinically, being transgender is ascertained on the basis of history alone. The patient should have both persistent gender incongruence and the capacity to make treatment decisions. The requirement for persistence does not have a specific time frame, but typical presentations include clarity regarding gender identity that extend back years—indeed commonly as far back as childhood. Reports of recognition of gender incongruence over shorter periods should prompt further exploration of underlying factors and goals.

Transgender persons also have higher rates of mental health morbidity, including anxiety, depression, and suicidality, often as a result of social stigma rather than gender incongruence per se. Patients should be screened for both confounding mental health issues and the ability to engage safely in treatment. Some mental health conditions may interfere with the ability to provide a reliable history. For example, patients who present as transgender might instead have an obsessive compulsive disorder or well-masked psychosis rather than true gender incongruence. Since transgender persons also can experience mental health morbidity, including obsessive-compulsive disorder and psychoses, a multidisciplinary assessment must include a careful evaluation of mental health.

Any sufficiently knowledgeable clinician should be able to ascertain that an adult is transgender. The criteria for determining whether someone is transgender are the same for children and adolescents as for adults. However, due to challenges in how children articulate gender identity, guidelines recommend including mental health professionals for assessment of minors. Clinicians also should be able to identify mental health conditions that might confound the assessment or that should include input from mental health providers who can.

ABSTRACT

Gender identity is the internal sense of one's own sex, whether male, female, neither, both, or something else. Transgender is a broad term to reference individuals with a gender identity that differs from sex recorded at birth, the latter typically based on external genitalia. Gender identity is a biologic phenomenon that cannot be influenced externally. For transgender people seeking medical intervention, treatment focuses on aligning the body with the gender identity by using hormones, surgeries, or both. Strategies for gender-affirming hormone therapy for adult transgender patients primarily involve moving circulating testosterone levels up for masculinizing therapy and down for feminizing therapy. Transgender people may consider a number of gender-affirming surgical interventions. Not all transgender people seek gender-affirming hormone therapy, and not all seek gender-affirming surgery either.

TREATMENT

Not all transgender persons seek medical treatment. Even among those who desire intervention, treatment may be deferred due to barriers that include family circumstance, work environment, or insurance coverage.

Persons who seek medical treatment for gender incongruence benefit from providers who can help set expectations about medical interventions. Primary care clinicians can initiate and manage transgender medical interventions, including both hormone therapy and other agents that affect hormone levels, with support from endocrinologists, if needed.[7]

No convincing literature indicates any success or benefit from attempts to change a person's gender identity. In fact, such effects to conform to sex norms result in demonstrably poorer psychosocial outcomes.

Mental health support is a key element of gender-affirming care. Clinicians must address mental health conditions that may confound assessment of gender identity and treatment goals.

The current strategies for gender-affirming hormone therapy for adult transgender patients primarily involve moving circulating testosterone levels up for masculinizing therapy and down for feminizing therapy.[8] Typical agents are androgens to virilize transgender men and estrogens, in addition to other antiandrogens given as adjuncts, to reduce testosterone levels to the conventional female range for transgender women while maintaining estradiol levels in what is considered the typical female physiologic range.

Prior to beginning gender-affirming hormone therapy, clinicians should review the patient's gender identity, treatment goals, and timing for therapy, with discussion of both social and health issues. Typical informed consent for shared medical decision making includes the potential risks and benefits of hormone therapy along with the time frame for expected changes. Clinicians should be knowledgeable about routine monitoring of hormone levels, monitoring of other relevant laboratory testing (e.g., serum potassium measurement for spironolactone treatment or hematocrit for testosterone treatment), and potential adverse outcomes. In the absence of specific data for transgender people, cancer screening is typically done on the basis of the tissues and organs present and informed by guidelines for the general population.

Hormone Therapy for Transgender Men (Female to Male)

Gender-affirming hormone treatment for transgender men (female to male) is very similar to hormone replacement therapy for hypogonadal cisgender men (Chapter 216), with testosterone, usually starting at a dose that is about half the dose used for a hypogonadotropic cisgender man (see Table 216-6) and aiming for a goal testosterone level in the typical physiologic cisgender male range (300 to 1000 ng/dL).[9] Testosterone can be administered orally, transdermally, or parenterally (Table 215-2). The most popular products are testosterone enanthate or cypionate 50 to 200 mg weekly administered intramuscularly or subcutaneously. Higher doses (100 to 200 mg) can be administered every 2 weeks, but patients may not prefer the resulting greater periodicity in testosterone levels. Transdermal preparations such as testosterone gel (2.5 to 10 g/day) or a testosterone patch (2.5 to 7.5 mg/day) will achieve the same virilizing effects as intramuscular testosterone, but poor absorption may prove frustrating when trying to achieve goal testosterone levels. Also, testosterone patches may cause skin irritation. Although not widely used, oral testosterone undecanoate (160 to 240 mg/day) is also available.[10] There is no indication for antiestrogens. Some patients, including some who identify as nonbinary, may ask to be treated with smaller doses of testosterone.

Although the exact effects and time course of testosterone will vary from patient to patient, responses to treatment include increased facial/body hair, male-pattern balding, increased acne, increased libido, increased muscle mass, clitoromegaly, deepening of the voice, and redistribution of fat within the first 3 to 12 months of testosterone therapy. Menses cease in the majority of individuals within 6 months of initiating treatment.[11] Although circulating sex hormone is needed for optimal bone health, there is no known health reason to prefer a typically male hormone profile versus a typically female hormone profile, or something in between. Even low-dose hormone treatment can have dramatic physical consequences for some people. Patients should be counseled and asked to state their desired outcome before beginning treatment.

Monitoring of Masculinizing Gender-Affirming Hormone Therapy

Patients taking testosterone are typically monitored both by laboratory testing and by clinical evaluation for virilizing and adverse effects approximately every 3 months for the first year, which corresponds to the recommended interval for dose titration, and then every 6 to 12 months once stability is achieved within the intended laboratory range. Patients taking testosterone enanthate or cypionate intramuscularly or subcutaneously can have testosterone peak levels measured 24 to 48 hours after injections and occasional trough levels measured immediately prior to injections. Alternatively, levels can be checked at the midpoint between doses. Patients taking transdermal testosterone can have levels sampled any time after 1 week of treatment.

Because androgens are known to stimulate erythropoiesis, the hematocrit (or hemoglobin) level should be monitored with dose titration and on occasion afterward. Dose adjustment and/or other intervention (e.g., phlebotomy) may be required if erythrocytosis is unmasked and a reversible explanation is not identified.

Because adequate levels of sex hormones are required to maintain bone density, patients should avoid hypogonadism.[12] Bone mineral density screening can be initiated at age 60 years or if testosterone levels are consistently low.

Contraindications to initiating testosterone therapy include pregnancy, unstable coronary artery disease, and untreated polycythemia (hematocrit ≥55%). Testosterone therapy may unmask polycythemia (Chapter 152) and hyperlipidemia (Chapter 190),[13,14] but both can then be treated appropriately.

Transgender men with cervixes or breast tissue should undergo age-appropriate cancer screening. Whether testosterone therapy puts transgender men at an increased risk for uterine or ovarian cancer is unknown. However, evidence is insufficient to recommend routine hysterectomy or oophorectomy in transgender men for the purpose of preventing malignancy.

Hormone Therapy for Transgender Women (Male to Female)

The goal in hormone therapy for transgender women is to decrease circulating total testosterone levels to the typical female range (<50 ng/dL)

TABLE 215-2 TESTOSTERONE THERAPY FOR TRANSGENDER MEN (FEMALE TO MALE)

MEDICATION	DOSE	CONCERNS	COMMENTS
TESTOSTERONE		Erythrocytosis, which may unmask polycythemia that may require further evaluation	Screen for tobacco use, sleep apnea
		Acne can develop and/or be exacerbated	Acne, typically transient
Parenteral			
Testosterone enanthate or cypionate	Start at 25 to 50 mg IM/SQ weekly or 50 to 100 every 2 weeks and titrate up to 50 to 100 mg IM/SQ weekly or 100 to 200 mg IM/SQ every 2 weeks		SQ or IM injections have been demonstrated to be equally effective Target levels are more easily achieved than with transdermal products Weekly administration diminishes periodicity Monitor levels either with peaks (at 24-48 hours) and troughs (immediately prior to next dose) or with mid-dose measurement
Testosterone undecanoate	1000 mg IM every 12 weeks	Oil embolism is a rare adverse event	
Transdermal or Transbuccal			
Testosterone gel	Start at 25 mg/day and titrate up to 50 to 100 mg/day	Risk of transfer to others	Uniform levels Target levels may be harder to achieve than with parenteral products
Testosterone patch	Start at 2 mg/day and titrate up to 8 mg/day	Skin reactions are common	Uniform levels Target levels may be harder to achieve than with parenteral products
Testosterone buccal patch	30 mg to gums every 12 hours		Inconvenience of preparation may limit use

IM = intramuscular; SQ = subcutaneous.

Adapted from Safer JD, Tangpricha V. Care of transgender persons. *N Engl J Med*. 2019;381:2451-2460.

while maintaining typically physiologic female levels of circulating estradiol. Exogenous estradiol can potently suppress testosterone levels via central feedback, but incorporating an adjunctive antiandrogen allows for lower doses of estrogen,[15] thereby limiting the dose-related risk of venous thromboembolism. Standard goals are typically achieved with a treatment that includes estrogen in combination with an adjunctive antiandrogen (Table 215-3).

Estrogen Therapy

Estrogens can be administered orally, transdermally, or parenterally. Oral conjugated estrogens (2.5 to 7.5 mg) and oral 17-beta estradiol (2 to 10 mg) daily are popular because they are easy to use and readily available, but estradiol is more commonly prescribed. Data suggest fewer thrombotic events in patients using transdermal patches.[16] Estradiol also can be administered parenterally as estradiol valerate or cypionate 5 to 20 mg intramuscularly every 2 weeks or 2 to 10 mg intramuscularly every week, but levels are more difficult to monitor. Each formulation may result in metabolites that can confound the measurement of hormone levels. Ethinyl estradiol should be avoided because of its increased risk of venous thromboembolism.

Patients should be counseled to expect decreased facial/body hair, decreased libido, decreased spontaneous erections, decreased skin oiliness, decreased muscle mass, redistribution of fat, and breast development within the first 3 to 12 months. Breast growth peaks after about 2 years of hormone therapy.[17]

As for transgender men, some patients, including some who identify as nonbinary, may choose to be treated with lower doses of medication. Some circulating sex steroid is needed for bone health, but there are no other known health reasons to prefer a typically male hormone profile versus a typically female hormone profile or something in between. Even low-dose hormone regimens can have dramatic physical consequences for some people, and patients should be counseled appropriately before embarking on treatment.

Adjunctive Antiandrogen Therapy

Spironolactone, which is the most commonly prescribed adjunctive antiandrogen agent because it is the least costly, is an aldosterone receptor antagonist that also inhibits the secretion of testosterone in some people. Spironolactone is most commonly administered in doses of 100 to 200 mg daily. Doses are not typically divided because the weak diuretic properties of spironolactone may cause nocturia.

Gonadotropin-releasing hormone (GnRH) agonists, such as leuprolide (3.75 mg subcutaneously monthly), inhibit the production of luteinizing hormone and follicle-stimulating hormone and therefore testosterone. GnRH agonists are the preferred adjunct to estrogens in the United Kingdom, but they are more expensive than spironolactone and must be given by injection.

Cyproterone acetate, which is a progestin, is the most popular adjunct gender-affirming hormone treatment in Continental Europe. However, among transgender women, cyproterone acetate has been associated with elevated prolactin levels, worsening lipid profiles, and rare meningiomas.[18]

Monitoring of Feminizing Gender-Affirming Hormone Therapy

Transgender women on hormone therapy can be monitored about every 3 months for the first year, corresponding to the interval for dose titration, and then every 6 to 12 months. Hormone therapy should be titrated to goal hormone levels in the typical physiologic female range (testosterone <50 ng/dL; estradiol <200 pg/mL) rather than a physical end point or subjective sense of feminization.

Because spironolactone is a potassium-sparing diuretic and can cause hyperkalemia in rare individuals, the serum potassium level should be checked when initiating spironolactone therapy and with changes in dose. Although guidelines often suggest monitoring serum prolactin levels, elevated prolactin levels have been noted only in patients using adjunct cyproterone acetate, not in patients using other adjunct treatments or patients using estrogens alone.[19]

Clinicians should be aware of the small but apparently slightly elevated potential for venous thromboembolism (Chapter 68) with exogenous estrogens.[20] In transgender women who have a history of venous thromboembolism, the preferred approach is to maintain the hormone treatment regimen and to follow prophylaxis protocols (Chapter 68).

Bone mineral density screening should be initiated by age 60 years but earlier if sex hormone levels are consistently low. Absent specific data for transgender individuals, transgender women should be screened for breast (Chapter 183) and prostate cancer (Chapter 186) according to current guidelines for cisgender individuals. Data suggest that the incidence of breast cancer is lower among transgender women than among cisgender women.[21] Prostate tissue remains even after vaginoplasty.[22]

Surgical Treatment for Transgender Individuals

As part of the approach to align bodies with gender identities, transgender people may consider a number of gender-affirming surgical interventions, which can help address the incongruence between sexual anatomy and gender identity.[23] Just as not all transgender people seek gender-affirming hormone therapy, not all seek gender-affirming surgery. Gender affirmation surgical options may be limited due to the small number of qualified medical facilities. Furthermore, patients may opt for one or more of the available surgical options in a customized fashion.

Surgeries for Transgender Men (Female to Male)

The most common surgery is chest reconstruction surgery to create a more masculine chest. The volume of parenchyma, position of the nipple-areola complex, and degree of skin elasticity all may influence the preferred surgical approach.[24]

Due to a high degree of morbidity along with a small pool of expert surgeons and resulting limited access, only a minority of transgender men will opt for genital reconstruction surgeries, which can combine removal of the vagina, uterus, and ovaries with either metoidioplasty or phalloplasty.[25] A metoidioplasty, which lengthens the hormonally hypertrophied clitoris, can be performed with or without lengthening the urethra. With urethral lengthening, the procedure may allow for voiding while standing. The ability to engage in penetrative intercourse following the procedure is limited.

A more complete genital reconstruction surgery is called phalloplasty. The typical approach uses a radial forearm free flap, thereby allowing for a

TABLE 215-3 HORMONE TREATMENT REGIMENS FOR TRANSGENDER WOMEN (MALE TO FEMALE)

MEDICATION	DOSE	CONCERNS	COMMENTS
ESTROGENS		Exogenous estrogens are associated with increased risk of thromboembolism	Ethinyl estradiol carries the greatest risk of venous thromboembolism (VTE) among estrogen products
Oral			
Estradiol (17β-estradiol)	Titrate to 2 to 10 mg/day		Most commonly used due to inexpensive cost and wide availability
Conjugated estrogens	Titrate to 2.5 to 10 mg/day		Levels of estrogen cannot be measured in blood by conventional assays
Transdermal			
Estradiol patch	Titrate to 0.1 mg/day to 0.2 mg/day		Associated with fewer VTE events than oral estrogens, but thrombosis data do not control for dose delivered
Parenteral			
Estradiol valerate	Titrate to 5 to 10 mg IM every week or 10 to 20 mg IM every 2 weeks		Can result in wide fluctuations in estradiol levels An alternative preparation is estradiol cypionate, which is less concentrated
ADJUNCTIVE ANDROGEN LOWERING OR INHIBITING AGENTS			
Spironolactone	Titrate to 100 to 300 mg/day orally	Hyperkalemia, dehydration	Potassium levels should be monitored when initiating therapy, when doses are changed, and annually thereafter
GnRH agonists (e.g., leuprolide)	3.75 to 7.5 mg IM or SQ monthly or 11.25 to 22.5 mg IM or SQ depot every 3 months		Use may be limited by cost and convenience
Cyproterone acetate	Titrate to 50 mg/day orally	May be associated with hyperprolactinemia and meningiomas	

IM = intramuscular; SQ = subcutaneous.

single-stage construction of a phallus and neourethra should lengthening of the urethra be desired. In an alternative approach, an anterior wall vaginal flap is used during phalloplasty, either without a lengthened urethra or with a lengthened urethra deferred to a future surgery. Both metoidioplasty and phalloplasty procedures may involve a scrotoplasty with testicular implants.

Surgical complications for genital reconstruction procedures occur in 40% or more of cases, often related to urethral strictures or fistulas in people who have had a urethral lengthening. Many of these patients will require subsequent urethroplasties.

Surgeries for Transgender Women (Male to Female)

Breast augmentation surgical approaches, which are similar to breast augmentation in cisgender women, are typically performed following 12 to 24 months of estrogen-induced breast growth. Laryngeal surgery or vocal feminization surgery shortens the vocal cords and better aligns the voice with gender identity.[26] Reduction thyroid chondroplasty removes excess cartilage found in the "Adam's apple," thereby causing it to be less prominent. Facial feminization procedures that might be considered cosmetic for cisgender women can be medically necessary for transgender women as key to being recognized safely as female. The typical genital reconstruction surgery is vaginoplasty, which is construction of a vagina, clitoris, and labia.[27] Penile inversion is the gold-standard technique. Following surgery, transgender women are required to dilate the neovagina indefinitely to maintain vaginal length. Dilation requirements may be less rigorous if intestinal tissue is used for vaginoplasty; however, intestinal vaginoplasty is less preferred because of increased secretion from the tissue. Perioperative pelvic floor muscle physical therapy can be useful. Orchiectomy is available to remove the source of endogenous testosterone when less surgery is desired.

Perioperative Hormone Management

Gender-affirming hormone therapy should be maintained throughout the perioperative period for most people. Transgender women can discontinue adjunct antiandrogens following vaginoplasty and/or orchiectomy.

Other Risk Considerations Connected to Gender-Affirming Hormone Treatment

Insulin resistance and changes in body fat may occur in both transgender men and women after initiating gender-affirming hormone therapy. The fact that both transgender men and transgender women are reported to share the same risk despite opposite treatment regimens may mean that the observation is not mediated by hormone treatment but rather simply reflects a secular trend.

There is no evidence of an overall increased risk of cancer related to hormonal therapy.[28] Periodic health evaluations for transgender individuals should include age-appropriate cancer screening for any tissue present. Prostate cancer has been documented in transgender women.[29] Both uterine and cervical cancer have been documented in transgender men. Breast cancer has been documented in transgender women and transgender men.[30]

PROGNOSIS

Preservation of Fertility

Gender-affirming hormone therapy and surgery may eliminate fertility. Postpubertal transgender women can consider sperm cryopreservation prior to engaging in gender-affirming medical treatment. For younger transgender girls, introducing GnRH analogue therapy later in puberty can facilitate sperm cryopreservation. Transgender boys may consider oocyte cryopreservation. Oocytes have been retrieved from transgender boys who had already started GnRH analogue therapy, and a live birth has been reported from a stimulated oocyte retrieved from a transgender man while he remained on testosterone with the embryo implanted in the uterus of his cisgender partner.

Although infrequent, some transgender people may discontinue gender-affirming hormone therapy or request reversal of gender-affirming surgical treatment to the degree such reversal is possible. Surveys suggest that the biggest reasons for such treatment change are pressures from work, family, and society. Rarely, people with mental health morbidity may receive gender-affirming treatment that was not indicated.

THE TESTIS AND MALE HYPOGONADISM, INFERTILITY, AND SEXUAL DYSFUNCTION

RONALD S. SWERDLOFF AND CHRISTINA WANG

MALE REPRODUCTIVE PHYSIOLOGY

The testis is a bifunctional organ that serves as the site for synthesis of sex steroids (mainly testosterone) and the production of sperm. Androgens and their metabolites (including estrogens) also act on nonreproductive organs and serve essential roles in muscle, adipose tissue, bone, hematopoietic cells, liver, and brain.

The male reproductive axis consists of three main components: (1) hypothalamus, where the kisspeptin-neurokinin B-dynorphin neurons are located and gonadotropin-releasing hormone (GnRH) is produced; (2) pituitary, where gonadotrophs secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and (3) testes, which produce sex hormones and spermatozoa (sperm) (Fig. 216-1). The components of this system function in an integrated fashion to control the concentrations of circulating gonadal steroids required for normal male sexual development and function, as well as for androgen- and estrogen-mediated effects on critical sex-steroid sensitive

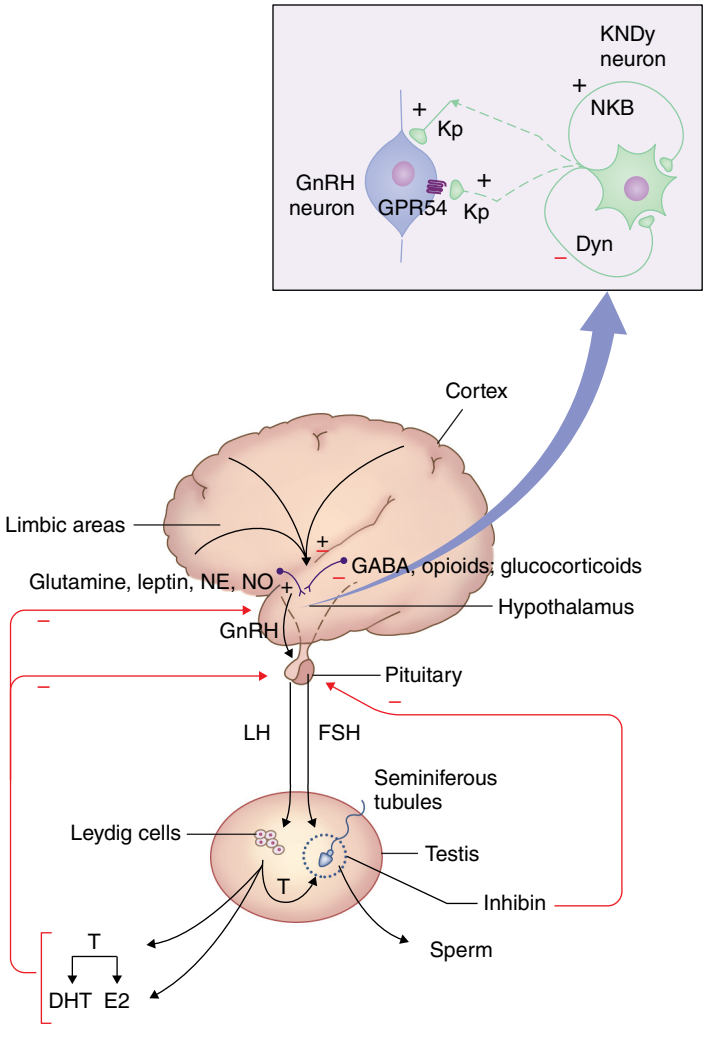

FIGURE 216-1. The hypothalamic-pituitary-gonadal axis in the male. *Inset*: The kisspeptin, neurokinin B, and dynorphin (KNDy) neurons in the hypothalamus. DHT = dihydrotestosterone; Dyn = dynorphin; E_2 = estradiol; FSH = follicle-stimulating hormone; GABA = gamma-amino butyric acid; GnRH = gonadotropin-releasing hormone; GPR54 = G-protein–coupled receptor 54; Kp = kisspeptin; LH = luteinizing hormone; NE = norepinephrine; NKB = neurokinin B; NO = nitric oxide; T = testosterone.

ABSTRACT

The hypothalamic-pituitary axis regulates testicular function, including spermatogenesis and the production of testosterone. The diagnosis of male hypogonadism is based on symptoms, the most common of which is sexual dysfunction. The diagnosis is confirmed by consistently low serum testosterone levels measured in the morning. Testosterone therapy can benefit men with low testosterone levels, but the potential risks should be discussed with the patient. The choice among available formulations of testosterone therapy should be made by the patient with advice from the physician depending on cost, availability, ease of use, and adverse effect profile. Many infertile men do not have a known cause for their infertility, but gene sequencing techniques can detect genetic deletions or mutations in up to 50% of such patients. Specific treatment with gonadotropins is available for infertility due to hypogonadotropic hypogonadism, whereas most other causes are not amenable to medical treatment. Use of assisted reproductive technology, including intracytoplasmic sperm injection with or without testicular sperm extraction, have allowed many men previously considered sterile to have a progeny. The most common sexual problem is erectile dysfunction, which is often a biomarker of cardiovascular disease. Treatment with a phosphodiesterase-5 inhibitor is effective therapy for most men with erectile dysfunction.

end organs. The reproductive axis is also responsible for normal male germ cell development and maturation. Accessory sexual organs, including the epididymides, seminal vesicles, and prostate gland, are important for sperm maturation (epididymis) and seminal fluid production (seminal vesicles and prostate). An anatomically functional sperm transport and ejaculatory system are necessary to ensure male fertility.

HYPOTHALAMIC-PITUITARY FUNCTION

The hypothalamus is responsible for the normal pulsatile secretion of GnRH (Chapter 205) that signals the anterior pituitary to release LH and FSH every 60 to 90 minutes in men. The secretion of GnRH is regulated mainly by kisspeptin, neurokinin B, and dynorphin neurons in the infundibular nucleus in the hypothalamus. Kisspeptin stimulates GnRH secretion directly, whereas neurokinin B stimulates kisspeptin neurons that in turn lead to GnRH secretion. In contrast, dynorphin has inhibitory effects on kisspeptin signaling.[1] Negative feedback from circulating levels of testosterone or its metabolic products (i.e., estradiol and dihydrotestosterone) inhibit the secretion and release of GnRH. Norepinephrine, nitric oxide, and glutamate stimulate this process, whereas gamma-amino butyric acid, prolactin, and glucocorticoid are inhibitory. Caloric restriction is associated with suppressed kisspeptin and leptin, which also are stimulants for GnRH secretion.

Both LH and FSH consist of two subunits (α and β), each of which is required for biologic activity. LH has a shorter half-life than FSH. Feedback regulation of LH and FSH secretion also occurs at the pituitary, with testosterone, dihydrotestosterone, and estradiol inhibiting the synthesis or release of both gonadotropins. The circulating testicular peptide inhibin, produced by Sertoli cells, also selectively inhibits FSH. LH and FSH act through specific cell surface receptors on the Leydig and Sertoli cells, respectively.

TESTOSTERONE

The testis is a complex organ consisting of (1) seminiferous tubules containing Sertoli cells and germ cells and (2) the interstitial space, which contains the steroid-secreting (Leydig) cells. Leydig cells synthesize steroid hormones under the regulation of LH. The LH receptors on the cell surface of the Leydig cells signal through G protein–, adenyl cyclase–, and cyclic adenosine monophosphate–mediated activation of steroid biosynthesis.

Testosterone is the principal male hormone secreted by the testes; approximately 5 to 10 mg/day is produced in adult men. Testosterone synthesis occurs in the human testes through either the Δ^4 or the predominant Δ^5 pathway The enzymatic rate-limiting steps in the process are the LH-inducible steroid acute regulatory protein and translocator protein that converts cholesterol to pregnenolone by the cholesterol side-chain cleavage enzyme (P450SCC) (E-Fig. 216-1).

Testosterone circulates mainly bound to two plasma proteins: sex hormone–binding globulin and albumin. In young adult men, approximately 54% of testosterone is bound to albumin, 44% is bound to sex hormone–binding globulin, and 2 to 3% is unbound (free). Bioavailable testosterone refers to the sum of albumin-bound and free testosterone and is measured by separating sex hormone–binding globulin–bound testosterone from total testosterone. Serum sex hormone–binding globulin levels are increased in hyperestrogenic states, hyperthyroidism, aging, phenytoin treatment, anorexia nervosa, and prolonged stress. In contrast, the levels are lowered in hyperandrogenic states (endogenous and exogenous as in androgen treatment), obesity, acromegaly, and hypothyroidism. In most instances, measurement of serum total testosterone provides biochemical support for the diagnosis of testosterone deficiency. In conditions with abnormal sex hormone–binding globulin levels, however, the total testosterone measurement may be misleading, and measurement of non–sex hormone–binding globulin–bound testosterone may allow better interpretation of the bioactive testosterone levels.

Testosterone exerts its effects either through direct action or after conversion to dihydrotestosterone by two separate 5α-reductase isozymes or to estradiol by the aromatase enzyme. Both testosterone and dihydrotestosterone bind efficiently to the androgen receptor. Testosterone also can serve as a precursor for estradiol, notably in bone and adipose tissues. After conversion, estradiol binds to the estrogen receptors (α or β) to induce its effects. Various end organs differ in their 5α-reductase isoenzyme and aromatase concentrations or activity. Congenital and acquired defects in these two enzymes, as well as in the estrogen and androgen receptors, result in distinct syndromes with characteristic phenotypes (Chapter 214).

SPERMATOGENESIS

The spermatogenic compartment of the testis consists of the Sertoli and germ cells that are intimately interactive with the interstitial compartment. The Sertoli cells bridge the entire space between the basement membrane and the lumen of the tubules. They are the target of androgen and FSH action to regulate spermatogenesis. Sertoli cells secrete a multitude of paracrine regulators of spermatogenesis (e.g., inhibin, activin, growth factors, and cytokines).

The development and maturation of germ cells depend on the proper hormonal (FSH) and paracrine (testosterone) milieu. Both testosterone and FSH stimulate progression of spermatogonia to mature spermatozoa, limit the amount of germ cell death (apoptosis), and regulate sperm release from the germinal epithelium.

After spermatogenesis is completed, mature spermatozoa are released into the lumen of the seminiferous tubule and travel through the rete testes and epididymis, where they become functionally mature, before traversing the vas deferens. The seminal fluid from the testes gains constituents from the seminal vesicles, prostate, and bulbourethral glands before ejaculation.

SEXUAL FUNCTION AND ERECTILE PHYSIOLOGY

Sexual function in men requires normal sexual desire (libido) as well as erectile, ejaculatory, and orgasmic capacity. This complex process involves cognitive, sensory, hormonal, autonomic neuronal, and penile vascular integrative actions for normal function. Defects can occur at multiple levels.

The brain is the integrative center of the sexual response system. It processes sensory input and hormonal signals to create the hypothalamic neuronal message that traverses the spinal cord to the T9-12 sympathetic and sacral parasympathetic outflow tracts. The nonadrenergic, noncholinergic autonomic plexus nerves initiate vasodilation of the cavernosal arterial and corpora cavernosal sinusoids of the penis by the release of local vasodilators (e.g., nitric oxide and vasoactive intestinal peptide) from the vascular endothelium and the sinusoidal smooth muscle cells of the sinusoids (E-Fig. 216-2). Nitric oxide produces smooth muscle dilation by the generation of cyclic guanosine monophosphate (cGMP) and the modification of calcium flux. The neurogenic mechanisms leading to vasodilation of the cavernosal arterioles and sinusoids result in a rapid increase in penile blood flow and expansion of the vascular channels; these effects inhibit venous return by compressing the venous channels against the tunica albuginea to limit venous drainage.

Testosterone's primary effect on erectile function is to enhance libido. Testosterone also increases penile nitric oxide synthase activity and enhances smooth muscle cell growth. Sexual desire and fantasy are highly sensitive to testosterone, thereby explaining the preservation of erectile capacity in many men with partial androgen deficiency.

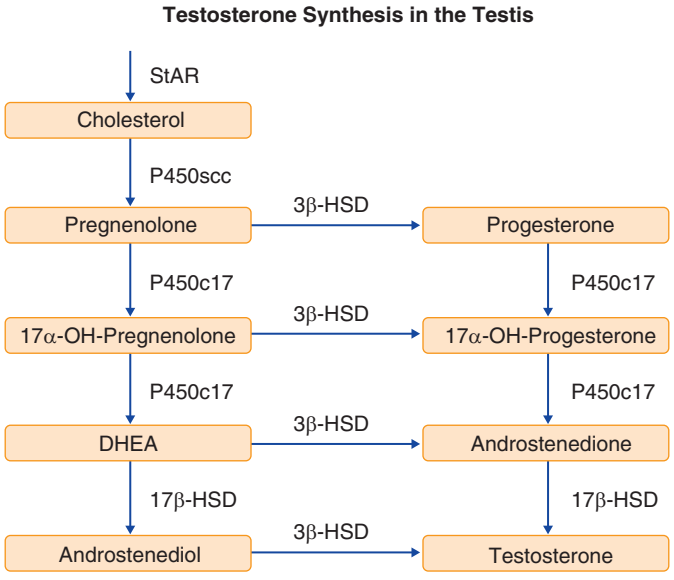
PUBERTAL DEVELOPMENT AND AGING

Reproductive Axis Development during Childhood and Puberty

Adrenarche and Puberty

Adrenarche occurs at approximately 7 or 8 years of age when the zona reticularis of the adrenal gland undergoes maturation and secretes adrenal androgens, including androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. The process is under the control of adrenocorticotropic hormone, not LH or FSH. Androstenedione and dehydroepiandrosterone are androgenic pre-hormones, and the prepubertal growth spurt and development of pubic and axillary hair are mediated by the conversion of these precursors to testosterone and dihydrotestosterone in peripheral tissues.

Initiation of puberty is determined by an increase in the pulsatile pattern of hypothalamic GnRH secretion. The secretory pulses of GnRH are synchronized by increased kisspeptin secretion from the hypothalamic neurons and nocturnal bursts of LH secretion.[2] As puberty progresses, feedback sensitivity of the hypothalamus and pituitary to circulating steroids lessens, thereby increasing the secretion of gonadotropins. The increasing concentrations of intratesticular testosterone and circulating FSH stimulate the Sertoli cell to produce factors leading to the initiation and maturation of spermatogenesis. As spermatogenesis advances, the first sign of puberty is marked by testes increasing in size from 3 to 5 mL at the outset of puberty to 15 to 35 mL in adulthood. The majority of the extratesticular end-organ events of puberty are secondary to the increased testosterone



E-FIGURE 216-1. The steroid acute regulatory *(StAR)* and translocator proteins mobilize cholesterol from cellular stores to the mitochondria. Intratesticular steroidogenic pathways for the synthesis of testosterone. Although both the Δ^5 *(left)* and Δ^4 *(right)* pathways exist, the Δ^5 pathway predominates in the human testis. DHEA = dehydroepiandrosterone; HSD = hydroxysteroid dehydrogenase.

TABLE 216-1 PUBERTAL STAGES IN BOYS

STAGE/AGE (YEARS)	PUBIC HAIR	GENITAL
I	Absence of pubic hair	Childlike penis, testes, and scrotum (testis 5.0 ± 3.6 cm^3)
II 11.7 ± 1.3	Sparse, lightly pigmented hair mainly at base of penis	Scrotum enlarged with early rugation and pigmentation; testes begin to enlarge (6.7 ± 3.5 cm^3)
III 13.2 ± 0.8	Hair becomes coarse, darker, more curled, and more extensive	Penis has grown in length and diameter; testes now 14.7 ± 6.3 cm^3; scrotum more rugated
IV 14.7 ± 1.1	Hair adult in quality, but distribution does not include medial aspect of thighs	Penis further enlarged, with development of glans; scrotum and testes (20.1 ± 6.2 cm^3) further enlarged
V 15.5 ± 0.7	Hair is adult and extends to thighs	Penis and scrotum fully adult; testes 29.3 ± 9.1 cm^3

Modified from Marshall WA, Tanner JM. Variation in pattern of pubertal changes in boys. *Arch Dis Child.* 1970;45:13-23; Daniel WA Jr, Feinstein RA, Howard-Peebles P, et al. Testicular volumes of adolescents. *J Pediatrics.* 1982:101:1010-1012.

and its metabolic products (dihydrotestosterone and estradiol) (Table 216-1). The penis and scrotum grow and become pigmented. A progressive increase is seen in facial, axillary, chest, abdominal, thigh, and pubic hair; frontal scalp hair regresses, and the voice deepens. Genital and sexual hair development and temporal scalp hair regression require dihydrotestosterone (DHT). The increased levels of sex steroids result in closure of the epiphysis and achievement of adult height.

Aberrations of Timing of Puberty

Delayed Puberty

Delayed puberty, more common in boys than in girls, is usually diagnosed when male sexual development has not begun by age 14 years. The majority of boys with delayed development have a functional hypothalamic–pituitary disorder and a family history of delayed puberty. Most eventually attain full sexual maturation when puberty is completed within 4.5 years.[3] Other causes of delayed puberty include genetic factors (congenital hypogonadotropic hypogonadism), prior chemotherapy or radiation therapy, malnutrition, excessive exercise, chronic illnesses, and diseases of the hypothalamus and pituitary.[4]

DIAGNOSIS

Careful documentation of changing physical findings and measurement of serum LH, FSH, and testosterone concentrations may provide valuable clues to the beginning of puberty. An increase in testicular size to more than 3 mL usually heralds the onset of puberty. Inquiring and testing for hyposmia or anosmia and other midline defects may indicate a common variant of congenital hypogonadotropic hypogonadism (e.g., Kallmann syndrome; Chapter 214).

TREATMENT

The decision to institute early treatment with testosterone (e.g., testosterone enanthate 10 mg subcutaneous injections every week or 20 mg intramuscular injections every 2 weeks, with the dose increased very slowly every 3 months) depends on the perceived degree of psychological stress associated with the maturational delay. The major concern is early fusion of the epiphyses induced by treatment with testosterone, which compromises optimal height; however, with judicious dosing and monitoring of bone age, this adverse effect is unusual. In adolescent boys with delayed puberty and low levels of gonadotropins, periodic withdrawal of treatment can determine whether spontaneous puberty has occurred. Many adult men diagnosed with and treated as adolescents for a presumed diagnosis of hypogonadotropic hypogonadism achieve normal reproductive function when they discontinue therapy.

Precocious Puberty

Precocious puberty in boys is defined as the onset of pubertal (secondary sexual characteristics) development before 9 years of age. Sexual precocity can be subcategorized as either true (central) isosexual precocious puberty or pseudo–precocious (peripheral) puberty.

Central or true precocious puberty is associated with increases in GnRH-stimulated LH and FSH secretion (hypothalamic–pituitary origin), whereas pseudo–precocious puberty (peripheral precocious puberty) is independent of GnRH stimulation of LH and FSH secretion. Central precocious puberty in boys is often associated with central nervous system (CNS) disease (two thirds of boys), including hypothalamic tumors, cysts, inflammatory conditions, and seizure disorders.

DIAGNOSIS

Diagnostic findings include sexual precocity, inappropriately elevated serum LH levels, and associated elevations of testosterone. Magnetic resonance imaging can localize most lesions. Another cause of central precocious puberty is human chorionic gonadotropin secretory germinomas (hypothalamic or pineal tumors). Pseudo–precocious puberty is characterized by increased testosterone with suppressed LH.

Causes of pseudo–precocious puberty include congenital virilizing adrenal hyperplasia, and testicular testosterone-secreting neoplasms. Constitutively active LH receptor mutations result in uncontrolled testosterone secretion (testotoxicosis).

TREATMENT

Treatment of true precocious puberty is removal or correction (with surgery or radiation therapy) of the CNS lesion, if possible, and treatment with GnRH analogues (e.g., leuprolide acetate 3-month depot 11.25 or 30 mg; or triptorelin, 6 month depot 22.5 mg every 6 months)[5] to suppress LH and FSH secretion temporarily. There is no consensus on optimal age to withdraw treatment, but between 11 and 11.5 years of chronologic age has been recommended. Treatment of peripheral precocious puberty depends on the cause but includes glucocorticoids (e.g., hydrocortisone 15 mg/m^2) for congenital virilizing adrenal hyperplasia and ketoconazole (10 to 20 mg/kg/day) to suppress steroidogenesis, with or without an antiandrogen (e.g., spironolactone 5 to 7 mg/kg/day or bicalutamide 2 mg/kg/day).

Male Senescence: Decreased Testosterone and Other Anabolic Hormones

Testosterone Deficiency in the Elderly

Blood concentrations of androgen pre-hormones (e.g., dehydroepiandrosterone, dehydroepiandrosterone sulfate) peak at approximately the third decade of life and then decline at about 2% per year, thereby resulting in levels that are 10 to 20% of baseline by 80 years of age.[6] As a result, both total and free serum testosterone levels also progressively decrease (E-Fig. 216-3) by as much as 1 to 2% per year. Serum sex hormone–binding globulin levels also rise with age in men, thereby resulting in a higher percentage of circulating testosterone that is tightly bound and causing a greater decline of free testosterone with aging. Older men have increased body fat, particularly visceral fat, and low testosterone levels are associated with comorbid conditions such as obesity and the metabolic syndrome.

In men between ages 40 and 70 years, the crude prevalence rate of symptomatic testosterone deficiency is estimated to be approximately 2 to 6%. Many of the effects of low testosterone levels in aging men are similar to those observed in younger hypogonadal men: decreases in libido, erectile function, muscle mass, muscle strength, bone mass, as well as impaired mood and sense of well-being.

TREATMENT

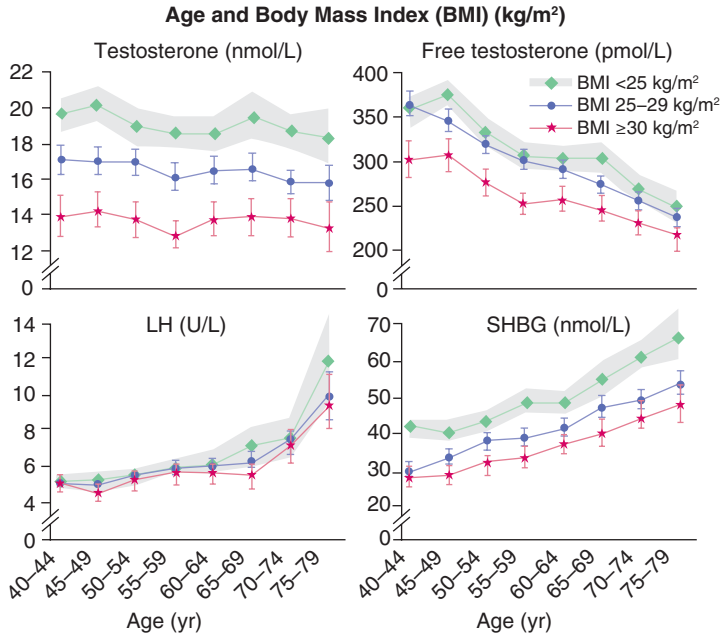
The decision of whether to treat low testosterone levels in older men is controversial. Testosterone treatment currently is not recommended to improve energy, vitality, physical function, metabolic syndrome, diabetes, or cognition (see Testosterone treatment).

MALE HYPOGONADISM

DEFINITION AND EPIDEMIOLOGY

Hypogonadism (androgen deficiency) is diagnosed in men with consistent symptoms and signs and unequivocally low circulating levels of testosterone. Most men with more severe androgen deficiency have very low intratesticular testosterone concentrations and are infertile.

The true prevalence male hypogonadism is not known[7] except for Klinefelter syndrome, which has a prevalence of about 5 per 10,000 men. Moderate to severe brain injury may also cause low testosterone with a prevalence probably about 5 per 10,000. Classic causes of male hypogonadism (e.g., pituitary



E-FIGURE 216-3. **Relationships among age, body mass index (BMI), and hormones.** The cohort was stratified according to BMI into three groups: nonobese (BMI < 25 kg/m^2), overweight (BMI 25 to 30 kg/m^2), and obese (BMI > 30 kg/m^2). Mean (95% CI in *shaded area* and *vertical lines*) total and free T and *SHBG* were significantly lower in the overweight and obese at all ages, compared with nonobese. The total T and SHBG age trends in the three BMI categories were similar (indicating no interaction between BMI and age); the free T age trend in the obese group was less steep than in the other two groups (indicating an interaction between BMI and age). Mean *LH* was not significantly different among the three groups at the median age of 60 years. LH was higher in the older than 70 years nonobese, compared with the overweight and obese groups, due to a negative BMI-age interaction. LH = luteinizing hormone; SHBG = sex hormone–binding globulin. (Wu FC, Tajar A, Pye SR, et al. Hypothalamic-pituitary-testicular axis disruptions in older men are differentially linked to age and modifiable risk factors: the European Male Aging Study. *J Clin Endocrinol Metab*. 2008;93:2737-2745.)

TABLE 216-2 CAUSES OF PRIMARY TESTICULAR FAILURE AND END-ORGAN RESISTANCE

Congenital disorders
Chromosome disorders, including Klinefelter and related syndromes (e.g., XXY, XXY/XY, XYY, XX males)
Testosterone biosynthetic enzyme defects
5α-Reductase deficiency
Androgen resistance syndrome
Myotonic dystrophy
Developmental disorders
Cryptorchidism
Acquired defects
Orchitis
Mumps and other viruses (including human immunodeficiency virus)
Granulomatous disease (e.g., tuberculosis, leprosy)
Infiltrative disease (e.g., hemochromatosis, amyloidosis)
Surgical, traumatic injuries, torsion of testis
Irradiation
Toxins (e.g., alcohol, fungicides, insecticides, heavy metals, cottonseed oil, DDT, other environmental "endocrine disruptors")
Drugs
Cytotoxic agents (alkylating agents)
Inhibitors of testosterone synthesis and antiandrogens (e.g., ketoconazole, abiraterone, cimetidine, flutamide, cyproterone, spironolactone)
Ethanol, opioids, other recreational drugs
Autoimmune testicular failure
Isolated
Associated with other organ-specific disorders (e.g., Addison disease, Hashimoto thyroiditis, insulin-dependent diabetes)
Systemic diseases* (e.g., cirrhosis, chronic renal failure, sickle cell disease,)
Aging*

*Systemic diseases and aging produce a mixed pattern of testicular and hypothalamic-pituitary dysfunction.
DDT = dichlorodiphenyltrichloroethane.

TABLE 216-3 CAUSES OF HYPOGONADOTROPIC HYPOGONADISM

IDIOPATHIC OR CONGENITAL
Isolated deficiency of gonadotropin-releasing hormone
With anosmia (Kallmann syndrome) or without anosmia
With other abnormalities (Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, basal encephalocele)
Partial deficiency of gonadotropin-releasing hormone (fertile eunuch syndrome)
Multiple hypothalamic and pituitary hormone deficiency
Pituitary hypoplasia or aplasia
ACQUIRED
Traumatic brain injury, after surgery or irradiation
Neoplastic
Pituitary adenoma (prolactinoma, other functional and nonfunctional tumors)
Craniopharyngioma, germinoma, glioma, leukemia, lymphoma
Pituitary infarction, carotid aneurysm
Infiltrative and infectious diseases of hypothalamus and pituitary (sarcoidosis, tuberculosis, coccidioidomycosis, histoplasmosis, syphilis, abscess, histiocytosis X)
Hemochromatosis
Autoimmune hypophysitis and cancer immunotherapy–induced hypogonadism
Aging and systemic diseases*
Obesity
Malnutrition
Anorexia nervosa, starvation, renal failure, liver failure
Exogenous hormones and drugs including opiates
Antiandrogens, estrogens and antiestrogens, progestogens, glucocorticoids, cimetidine, spironolactone, digoxin, drug-induced hyperprolactinemia (metoclopramide, tranquilizers, antihypertensives)

*Aging and systemic diseases produce a mixed pattern of central and testicular dysfunction.

tumors, iron overload) are probably rare, seen in less than 1 per 10,000 men. Iatrogenic causes, including systemic chemotherapy and testicular and pituitary radiotherapy, are the most common etiologies of male hypogonadism other than age and obesity.

PATHOBIOLOGY

Primary hypogonadism, which is characterized by increased serum LH and FSH levels, indicates that the abnormality originates in the testis.[8] Secondary hypogonadism indicates a defect of the hypothalamus (Chapter 204) or anterior pituitary (Chapter 205), thereby resulting in decreased gonadotropins (LH, FSH, or both).

Many conditions can cause primary (Table 216-2) and secondary (Table 216-3) hypogonadism (see also Chapter 214). Combined primary and secondary hypogonadism occurs in aging and in a number of systemic diseases, such as alcohol abuse disorder (Chapter 364), liver disease (Chapter 132), type 2 diabetes mellitus (Chapter 210), human immunodeficiency virus (HIV) infection (Chapter 359), hemochromatosis (Chapter 196), and sickle cell disease (Chapter 149). Obesity (Chapter 201) leads to low total and free testosterone levels, with greater decreases in the total testosterone level because obesity not only decreases testosterone secretion but also lowers sex hormone–binding globulin levels. Decreased androgen action with normal or elevated testosterone and LH levels, mimicking androgen deficiency, may occur in patients with androgen receptor defects (androgen resistance), post-receptor signaling abnormalities, and an inability to convert testosterone to the active metabolite dihydrotestosterone (5α-reductase abnormalities).

Primary Testicular Hypogonadism

Primary hypogonadism is androgen deficiency, with or without infertility, in which the pathologic process lies at the testis level. (See Table 216-2.)

Congenital Defects

The most common congenital defect is due to chromosomal abnormalities (Klinefelter syndrome) and chromosomal translocations that are the leading causes of congenital male infertility (Table 216-2 and Chapter 214). Androgen-resistant states mimic testosterone deficiency clinically, but testosterone levels are normal or elevated. Causes of androgen resistance include genetic defects in the androgen receptor, congenital post–androgen receptor signaling defects, or 5α-reductase deficiency (Chapter 214).

Cryptorchidism[9] affects 2 to 9% of full-term newborn boys. Though testosterone deficiency is unusual, men with undescended testis have defects in spermatogenesis and an increased incidence of testicular cancer. Early surgical correction may improve fertility but does not reduce the risk of testicular cancer.

Acquired Defects

Infections

After puberty, mumps (Chapter 340) is associated with clinical orchitis in about 25% of cases, about 80% of which are unilateral. In the 20% of cases that are bilateral, a reported 30 to 90% of patients become infertile. The testes are inflamed, painful, and swollen during acute orchitis, and then gradually decrease in size. The testes may return to normal size and function, or they may atrophy. Spermatogenic defects occur more often and earlier than Leydig cell dysfunction, so patients with post-orchitic infertility may have normal testosterone and LH levels with increased serum FSH levels. Over time, elevations in LH and lower serum testosterone levels may appear. Leprosy (Chapter 301) also may cause orchitis and gonadal insufficiency. HIV infection is often associated with hypogonadism, which can be either hypogonadotropic or hypergonadotropic.

Trauma and Irradiation

The exposed position of the testes in the scrotum makes them particularly susceptible to injury, which may require emergency surgical intervention to prevent permanent testicular atrophy. Bilateral testicular torsion can result in ischemic testes that require surgery and result in androgen deficiency and infertility. Surgical injury during scrotal surgery for hernia, varicocele, and vasectomy can result in permanent testicular damage. Exposure of the testes to irradiation in the treatment of malignant diseases (e.g., testicular cancers) produces testicular germ cell, and less commonly, Leydig cell damage.

Drugs and Toxins

Chemotherapy, in particular alkylating agents, such as cyclophosphamide and busulfan, frequently leads to irreversible damage to germ cells. Heavy metals (lead, cadmium; Chapter 20) cause damage to the germ cells. Leydig cells are relatively less susceptible to most chemotherapeutic drugs than are Sertoli and germ cells. Some medications may interfere with testosterone biosynthesis (e.g., ketoconazole, abiraterone, spironolactone) or action (e.g., cyproterone, flutamide). Ethanol (Chapter 364), independent of its role in causing liver disease, inhibits the biosynthesis of testosterone. Marijuana, heroin, methadone (Chapter 365), medroxyprogesterone acetate, other progestins, and estrogens lower testosterone, mainly by decreasing LH. Medical treatment with androgens such as testosterone, dihydrotestosterone, and

synthetic anabolic steroids or their illicit use (e.g., in athletes, bodybuilders) lowers serum LH and FSH as well as sperm counts. Serum testosterone levels are low after the use of dihydrotestosterone and synthetic anabolic agents. Environmental toxins such as fungicides and insecticides (e.g., DBCP, metabolites of DDT, vinclozolin) and byproducts of the plastics industry (e.g., phthalates, bisphenol A) are called "endocrine disruptors" because these chemicals may have either weak estrogenic or antiandrogenic effects and can cause testicular dysgenesis in male offspring when administered in large doses to pregnant female rodents. Data linking "endocrine disruptors" to male reproductive dysfunction in humans are principally association studies and do not prove causality.

Autoimmune Testicular Failure

Antibodies against the microsomal fraction of the Leydig cells may occur either as an isolated disorder or as part of a multiglandular disorder (Chapter 212) involving, to variable degrees, the thyroid, pituitary, adrenals, pancreas, and other organs.

Secondary Gonadal Insufficiency (Hypogonadotropic Hypogonadism)

Congenital Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism represents a deficiency in the secretion of gonadotropins (LH and FSH) because of an intrinsic or functional abnormality in the hypothalamus or pituitary glands (see earlier and Chapter 214). Congenital hypogonadotropic hypogonadism is caused by mutations of genes that regulate the GnRH neurons or secretion of GnRH. For example, hypogonadism, Kallmann syndrome, is associated with anosmia or hyposmia and other anomalies.[10] Genetic abnormalities of the regulation kisspeptin/neurokinin B/dynorphin release by hypothalamic neurons result in secondary Leydig cell dysfunction (see Table 216-3). The clinical manifestations depend on the age of the patient at the onset of the disorder and manifestations due to the genetic defects.

Acquired Hypogonadotropic Disorders

Anorexia Nervosa and Weight Loss

Starvation, anorexia nervosa (Chapter 200), and weight loss are examples of functional defects that result in hypogonadotropic hypogonadism with low serum testosterone levels. Strenuous exercise usually has minimal effects on testicular function, but functional hypogonadotropic hypogonadism can be caused by chronic excessive exercise.[11]

SYSTEMIC DISEASES

Severe stress (e.g., surgery, trauma) and systemic illness also lower gonadotropin and testosterone levels. Abnormalities of the hypothalamic-pituitary-testicular axis occur in a number of systemic diseases, including liver failure, renal failure, sickle cell anemia, advanced malignant disease, severe obesity, metabolic syndrome, type 2 diabetes, cystic fibrosis, amyloidosis, granulomatous and infiltrative diseases, and post-traumatic lesions in the region of the hypothalamus and pituitary (Chapter 205).

The effects of cirrhosis of the liver on testicular function are complex and may be either independent of or associated with the direct toxic effects of the continued use of alcohol. Gynecomastia, testicular atrophy, and impotence are concomitant signs of cirrhosis. Decreased spermatogenesis with peritubular fibrosis occurs in 50% of cases. Estradiol levels are usually elevated, thereby resulting in an increased ratio of serum estradiol to testosterone, often associated with gynecomastia. In sickle cell anemia and thalassemia major, boys may have impaired sexual maturation, and men are often infertile. Hemochromatosis (Chapter 196) may affect the hypothalamus-pituitary, as well as act directly on the testis. Diabetes and obesity are two major factors in hypogonadism. Emerging data show that type 2 diabetes is associated with low blood testosterone levels mainly as a result of hypothalamic-pituitary dysfunction; the decrease in serum testosterone correlates with the degree of hyperglycemia.

Pituitary Tumors

In men, prolactinomas (Chapter 205) are usually large (>1 cm in diameter; macroadenomas) by the time they are detected. Male patients with prolactin-secreting macroadenomas usually present with hypogonadism, erectile dysfunction, and visual field defects from suprasellar extension. In small tumors, hypogonadotropic hypogonadism may be due to suppressed GnRH levels, but the mass effect of large tumors can directly damage the non-neoplastic gonadotrophs. Large non–prolactin-secreting pituitary tumors (growth hormone, adrenocorticotropic hormone, glycopeptide, and null cell; Chapter 205) also may produce gonadotropin insufficiency when damage to the adjacent normal pituitary gland results in decreased serum LH and testosterone levels.

Autoimmune Hypophysitis

Autoimmune hypophysitis (Chapter 204) affects the pituitary and/or the infundibulum, thereby resulting in enlargement of the pituitary gland that may spontaneously involute or require pharmacologic treatment of the inflammation to prevent hypogonadotropic hypogonadism.[12] Cancer immunotherapy with checkpoint inhibitors (Chapter 164) may induce hypophysitis, thereby resulting in secondary adrenal, thyroid, and gonadal insufficiency. Recovery from central hypogonadism is more common than recovery from secondary adrenal or thyroid insufficiency.

CLINICAL MANIFESTATIONS

In children and adolescents, the most specific symptom of low testosterone is incomplete or delayed puberty. The most common symptoms of testosterone deficiency in adult men are sexual dysfunction, but decreased sexual drive and interest may precede erectile dysfunction. Other symptoms are loss of body hair, breast discomfort and enlargement, subfertility, hot flashes, sweat, and loss of height. Other nonspecific symptoms include decreased energy and mood, poor concentration, increased abdominal fat, and decreased muscle mass.

DIAGNOSIS

The diagnosis of hypogonadism is based on clinical symptoms and signs and a reduced serum testosterone level, compared with a normal reference range in healthy, young adult non-obese population (reported range for European and American men age 19 to 39 years, is 264 to 916 ng/dL).

History

The medical history should focus on testicular descent, pubertal development, shaving frequency, changes in body hair, and present and past systemic illnesses. A complete sexual history includes changes in libido, erectile and ejaculatory functions, frequency of masturbation, coital activity, and fertility (including that of present and previous partners). Information should be obtained on previous orchitis, sinopulmonary complaints, sexually transmitted diseases, human immunodeficiency virus (HIV) status, genitourinary infections, and previous surgical procedures that might affect the reproductive tract (e.g., orchiectomy, vasectomy, hernia repair, prostatectomy, varicocele ligation). Social history includes tobacco and alcohol intake. Medication and self-prescribed drug history includes recreational drugs; opioids; anabolic steroids; glucocorticoids; 5α-reductase inhibitors; psychiatric, antihypertensive, anti-androgenic, cytotoxic, and alternative medicine therapies; environmental toxins; and exposure to heat (including saunas and Jacuzzis), pesticides, and irradiation.

Physical Examination

The general physical examination includes height and span measurements; characterization of facial, pubic, and body hair distribution; presence of acne and facial wrinkling; breast examination for gynecomastia; assessment of muscle mass and adiposity; measurement of penile length and urethral meatus localization; digital rectal prostate examination; and visual field assessment if secondary hypogonadism is suspected. The scrotal examination should include an assessment of midline fusion (e.g., bifid scrotum, hypospadias); testicular size and consistency; presence of intratesticular masses; abnormalities of the epididymis; bilateral presence of vas deferens; and varicoceles, hydroceles, or hernias. Normal testicular volume is generally above 15 mL. Asian men have a slightly smaller mean testicular size. A decrease in testicular volume usually implies decreased spermatogenic cells because the seminiferous tubules account for more than 80% of testicular volume.

Laboratory Studies

Because of the strong diurnal rhythm in testosterone secretion in young men (highest in the morning), testosterone, LH, and FSH should be determined from morning blood samples (before 10 AM). Total testosterone measurements may be misleading indicators of Leydig cell secretory status in conditions in which sex hormone–binding globulin levels are abnormal (see earlier section). In these circumstances, measurement of free testosterone (using an equilibrium dialysis method), bioavailable testosterone (free plus albumin-bound), or calculated free testosterone (by total testosterone and sex hormone–binding globulin measurements) may be useful.

Elevated LH and FSH levels distinguish primary from secondary hypogonadism (both have low serum testosterone levels), but many older men with low serum testosterone levels may have a normal LH concentration. Serum

prolactin levels should be measured in all patients with low testosterone and low LH (hypogonadotropic hypogonadism) levels, as well as in men with known pituitary mass lesions, or galactorrhea. Dihydrotestosterone is measured in cases of abnormal differentiation of the genitalia and when 5α-reductase deficiency is suspected. Serum estradiol should be measured in cases of gynecomastia. Assessment of other testosterone precursors and products may be required in special circumstances, including suspected congenital adrenal enzyme defects.

If a young to middle-aged man has a morning serum total testosterone level that is repeatedly below 230 ng/dL (8 nmol/L), and he has symptoms or signs compatible with low testosterone state, the patient is probably hypogonadal, and testosterone replacement is indicated. If the serum testosterone level is between 230 and 320 ng/dL with normal serum LH levels, the patient may or may not be clinically hypogonadal, and androgen replacement may not improve the symptoms (e.g., sexual dysfunction). Thus, when serum total testosterone is borderline and LH is not increased, one of the measurements of bioactive testosterone is indicated (e.g., free testosterone). Because sex hormone–binding globulin levels are often increased, total testosterone levels may overestimate the biologically active forms. A serum total testosterone level above 350 to 400 ng/dL indicates that hypogonadism is very unlikely to be the cause of the symptoms, and the clinician should look for other explanations for the symptoms.[13]

TREATMENT

Indications

The main medical indication for androgen replacement therapy is male hypogonadism (Table 216-4).[14] In approximately 10% of men whose congenital or idiopathic hypogonadotropic hypogonadism reverses after testosterone therapy, the reversal is sustained after therapy is stopped. As a result, testosterone replacement should be periodically withdrawn, with serum testosterone and gonadotropins levels reassessed off therapy to be sure testosterone is still required. This phenomenon suggests that some patients with low serum testosterone due to hypogonadotropic hypogonadism may have a transient cause of the deficiency.

In younger men with symptomatic testosterone deficiency, testosterone replacement is indicated and has proven benefits.[15] At present, testosterone treatment usually is not recommended to improve energy, vitality, physical function, or cognition or for treatment of obesity or type 2 diabetes.[16–19]

Benefits and Risks of Testosterone Replacements

In hypogonadal men, androgen replacement leads to the development and maintenance of secondary sexual characteristics. In older men with relatively low serum testosterone levels, testosterone replacement therapy (up to 3 years) decreases fat mass, increases lean body mass, improves strength, and increases bone mineral density.[A1] When treatment with testosterone is sufficient to raise serum testosterone levels to the mid-normal young male range, patients report improved sexual activity libido, erectile function, and mood[A2–A4] with correction of unexplained anemia,[A5] and increases in bone mineral density and strength (Table 216-5).[A6] The effect on physical activity is modest at best, and no improvement is seen in cognition.[A7]

In hypogonadal men, testosterone treatment increases systolic blood pressure by up to 5 mm Hg. Testosterone-treated men also have significantly increased noncalcified plaque volume by coronary computed tomographic angiography,[A8] but cardiovascular adverse events have not increased over about a 3-year duration of the various randomized trials.[A9] In cohort studies with longer-duration follow-up, however, the data on cardiovascular risk are less clear.[20] Testosterone replacement therapy does not appear to affect lower urinary tract symptoms.[A10] It has no major short-term effects on the prostate gland but increases prostatic volume by an average of about 4.5 mL after 12 months in hypogonadal men. Whether testosterone treatment increases the risk of prostate cancer or of its invasiveness is uncertain. However, prostate cancer is androgen dependent, so testosterone treatment should be discontinued once prostate cancer is diagnosed.

Absolute contraindications to androgen replacement therapy include carcinoma of the prostate and the male breast. Androgens should be used with caution in older men with an enlarged prostate and urinary symptoms, elevated hematocrit, and sleep-related breathing disorders. A digital rectal examination should be performed, prostate-specific antigen level determined, and symptoms of severe urinary tract obstruction evaluated following urology standard practice before testosterone treatment is instituted in middle-aged and older men.

In older men with dehydroepiandrosterone deficiency, oral replacement with dehydroepiandrosterone raises serum dehydroepiandrosterone and dehydroepiandrosterone sulfate concentrations to the levels found in young men. However, serum testosterone levels do not change, and patients have not reported beneficial effects on quality of life, sexual function, mood, body composition, or exercise capacity.

TABLE 216-4 INDICATIONS FOR ANDROGEN THERAPY

Androgen deficiency (hypogonadism) with symptoms, signs, and a low testosterone level
Microphallus (neonatal)
Delayed puberty in boys
Angioneurotic edema
Other possible uses or under investigation
Hormonal male contraception
Sarcopenia associated with cancer, human immunodeficiency virus infection, chronic infection, frailty in older men and women

TABLE 216-5 ANDROGEN THERAPY: RISKS VERSUS BENEFITS

BENEFITS	RISKS
Development or maintenance of secondary sex characteristics	Fluid retention
Improved libido and sexual function	Gynecomastia
Increased muscle mass and strength	Acne, oily skin
Increased bone mineral density	Increased hematocrit, erythrocytosis
Improves anemia	Decreased high-density lipoprotein cholesterol (oral agents produce more effect)
Decreased body and visceral fat	Sleep apnea
Improved mood	Aggressive behavior (?)
Effect on cognition (?)	Prostate disease
Effect on vitality and quality of life (?)	Benign prostatic hyperplasia (?)
	Carcinoma of prostate (aggravate existing cancer)
	Increased cardiovascular adverse events (?)

Testosterone Delivery Systems

Testosterone treatment can be provided via different routes of administration (Table 216-6). Hydroalcoholic and nonalcoholic testosterone gels and lotions are the most widely used testosterone formulations in the United States. The usual[21] dosage is 50 to 100 mg of 1, 1.62, and 2% testosterone gel applied daily to the skin to deliver 5 to 10 mg of testosterone to the body. Transdermal delivery as gels or creams results in a more consistent serum concentration and causes little skin irritation. Transfer from the user to other people is possible during routine use and may be a concern if there is close skin contact with women and children. Protective clothing or a shower is necessary to avoid transferring testosterone through skin-to-skin contact. Testosterone gel also can be administered into the nose three times a day to provide sufficient concentrations of testosterone without a similar risk of transfer to other people. Transdermal testosterone patches deliver levels of testosterone within the normal range but have a high incidence of skin irritation (redness, swelling, and blisters). Testosterone esters, such as testosterone enanthate (or cypionate), are administered as intramuscular (150 to 200 mg once every 2 to 3 weeks, with resulting peaks and troughs of serum testosterone), whereas weekly subcutaneous injections (50 to 100 mg) result in more stable testosterone levels and are easier to use compared with intramuscular injections. Testosterone undecanoate injections (750 mg every 10 weeks or 1000 mg every 12 weeks after a second injection 4 or 6 weeks after the first injection) are the preferred replacement therapy in many parts of the world but not in the United States because of the regulatory requirement for 30 minutes of observation period after injection for cough episodes.

Oral options include testosterone undecanoate capsules (containing from 158 to 396 mg testosterone undecanoate in a self-emulsifying drug delivery system or 225 mg in a predigested triglyceride solution) twice daily with food.[22] Transbuccal testosterone (30-mg mucoadhesive tablets applied twice daily) results in physiologic-range testosterone levels by direct absorption into the systemic circulation, thereby avoiding first-pass effects on the liver. Modified 17α-alkylated androgens (methyl testosterone and many anabolic steroids), which are available in oral preparations, are not recommended as androgen replacement because they may lead to abnormalities in liver function, marked decreases in high-density lipoprotein cholesterol, and increases in total cholesterol levels compared with the testosterone esters.

Implants (pellets) of crystalline testosterone (75 mg/pellet) can maintain physiologic testosterone for 4 to 6 months depending on the number of pellets that are inserted subcutaneously. Implants are gaining popularity with U.S. urologists and are widely used in Australia and the United Kingdom.

TABLE 216-6 ANDROGEN PREPARATIONS

ROUTE	PREPARATION	DOSE AND FREQUENCY OF ADMINISTRATION
Transdermal gels	(AndroGel or Testogel; Testim; Axiron; Fortesta; Vogelxo)	1-2% gel (in packets or pumps) applied once daily delivering 50-100 mg testosterone on skin and 5-10 mg to body
Transdermal patch	Nonscrotal patch (Androderm)	Two patches, each delivering 2 mg/day; testosterone or one patch delivering testosterone 4 mg/day
Buccal/Nasal	Transbuccal testosterone, mucoadhesive tables (Striant)	30 mg two times daily
	Nasal gel (Natesto)	5.5 mg into each nostril three times/day
Injection	Testosterone enanthate (Delatestryl)	100 mg/wk IM or 150-200 mg IM every 2 wk
	Testosterone cypionate (Depo-Testosterone)	50-100 mg/wk SQ
	Testosterone undecanoate (Aveed)	750-1000 mg IM every 10-12 wk
Oral*	Testosterone undecanoate (Jatenzo, Tlando)	Jatenzo 158-396 mg or Tlando 225 mg PO two times daily with food
Implant	Testosterone implants (Testopel)	75-mg pellets (in United States), 6-10 pellets inserted once every 4-6 months

*Oral modified 17α-alkylated androgens such as methyltestosterone, fluoxymesterone, oxymetholone, stanozolol, and oxandrolone are not recommended for the treatment of androgen-deficient states because of potential hepatotoxicity and adverse effects on serum lipids.
IM = intramuscular; PO = oral; SQ = subcutaneous. Parenthesis (Registered Name).

MALE INFERTILITY

DEFINITION AND EPIDEMIOLOGY

Infertility is defined as the failure of a couple to achieve pregnancy after at least 1 year of frequent unprotected intercourse. If a pregnancy has not occurred after 3 years, infertility will most likely persist without medical treatment.

In the United States and Europe, the 1-year prevalence of infertility is 15% of couples. The prevalence in developing countries is likely to be higher because of the higher prevalence of genital tract infection. Of subfertility cases, 30 to 35% can be attributed to predominantly female factors, 25 to 30% to male factors, and 25 to 30% to problems in both partners.

PATHOBIOLOGY

Testicular disorders are the most frequent identifiable cause of male infertility (see Table 216-2), whereas hypothalamic-pituitary disorders are infrequent causes. The epididymis is the main location for sperm maturation, and lumicrine factors produced by germ cells appear to be critical to this process. Perturbations in these pathways may explain many cases of male infertility, and agents to interrupt it could become future male contraceptives.

With the advent of exome and whole-genome sequencing up to 50% of male infertility patients can now be diagnosed with genetic causes. Chromosomal disorders and translocations and Y chromosome microdeletions are increasingly recognized as a genetic cause of azoospermia and severe oligozoospermia. Up to 25% of infertile men have microdeletions in the long arm of the Y chromosome, many of which map to the Yq11 region of the chromosome, which is called the azoospermic factor (AZF). Mutations in the *AZFa* and *AZFb* regions are associated with azoospermia, whereas mutations of *AFZc* region may be associated with oligozoospermia. The gr/gr deletion removes a large segment of the *AFZc* gene and represents a significant risk factor for oligozoospermia in some but not all populations. Mutations in the testis-expressed 11 gene *(TEX11)* and many other newly discovered genes, such as *STAG3* and *DMRT1,* have been described as common causes of meiotic arrest and azoospermia in infertile men. Other genetic alterations cause ciliary dyskinesia, multiple flagellar abnormality, and sperm head defects. Y chromosome and other genetic defects may be transmissible to male offspring if patients are successfully treated with assisted reproductive technologies. Thus, genetic testing and counseling is important before technologies such as intracytoplasmic sperm injection are considered.

CLINICAL MANIFESTATIONS

The infertile man has no clinical manifestations, unless he has hypogonadism and seeks treatment for the symptoms of low testosterone. Usually, the female partner seeks medical advice when she fails to conceive after stable relationships with a male partner for 1 or 2 years (Chapter 218). A semen analysis ordered by the gynecologist identifies possible male factor infertility.

DIAGNOSIS

The approach to the diagnosis of an infertile couple includes management of both the male and the female partner (Figs. 216-2 and 216-3), often concurrently.[23,24] The history and physical examination should follow the recommendations for hypogonadism. Careful testicular examination should be performed by a skilled examiner to exclude a varicocele and for the presence of the vas deferens.

Examination of the ejaculate is the cornerstone for the investigation of an infertile man (Table 216-7). Semen samples are collected, preferably at the physician's office, after 2 to 7 days of abstinence from ejaculatory activity. The generally accepted reference values for a semen analysis (Table 216-8) represent the lower 5th percentile for semen parameters from data obtained population studies of fertile men and includes sperm concentration of 16 million/mL or higher; total sperm number of 39 million per ejaculate or higher; sperm motility of 42% or higher; and progressive motility of 30% or higher. Using strict criteria to assess sperm morphology, the percentage of morphologically normal forms is 4% or greater. Nevertheless, men with semen parameters below the 5th percentile of fertile men can be fertile, and the sperm quality of fertile and subfertile men overlaps considerably.[25] Low sperm concentration or poor sperm morphology is associated with lower chances of natural conception in the female partner. In patients with abnormal semen analyses, measurements of serum FSH, LH, and testosterone are indicated (see Fig. 216-2). Elevated FSH levels usually indicate severe germinal epithelial damage. A decreased serum inhibin B level or low antimüllerian hormone concentration reflects poor Sertoli cell function and may indicate spermatogenic dysfunction (commonly called non-obstructive azoo-spermia or oligozoo-spermia). Elevated serum LH and FSH concentrations together with a low serum testosterone level indicate pan-testicular failure with hypogonadism and infertility. Low serum FSH, LH, and testosterone concentrations indicate hypothalamic-pituitary dysfunction; serum prolactin should be measured, and additional investigations may be required. A low sperm concentration and suppressed LH level with an increased, normal, or low serum testosterone level (without clinical manifestations of androgen deficiency) may suggest exogenous androgen use. The hormonal pattern in androgen insensitivity (an uncommon cause of male infertility) is elevated LH, normal FSH, and high-normal to increased serum testosterone levels. Normal hormonal parameters (see Table 216-7) in azoospermic (no sperm in the ejaculate) men with normal-sized testes may suggest congenital or acquired obstruction in the epididymis or vas deferens (obstructive azoospermia).

TREATMENT

Correction of a varicocele appears to increase fertility and is worthwhile, even though it may not result in fertility.[26] The approach to the treatment of male infertility (see Figs. 216-2 and 216-3)[27] can be summarized in four categories. First, men with mild-to-moderate oligozoospermia, with or without decreased sperm motility and some impairment of motility, are subfertile rather than infertile. Spontaneous pregnancies can occur, but assisted reproductive technologies, including in vitro fertilization and intracytoplasmic sperm injection, have dramatically improved pregnancy rates. Second, reliable pharmaceutical treatment is limited to the 1 to 2% of infertile men with gonadotropin insufficiency. Third, in male factor infertility, azoospermia (absence of sperm in the ejaculate) may occur with obstruction of the ejaculatory system. In azoospermic patients who have had a prior vasectomy and who may for various reasons desire pregnancy of their partner, epididymovasostomy achieves patency in 90% of men, but pregnancy occurs in only about 50% of their female partners. In these patients, in vitro fertilization, and intracytoplasmic sperm injection after either percutaneous epididymal sperm extraction or microsurgical epididymal sperm extraction are highly

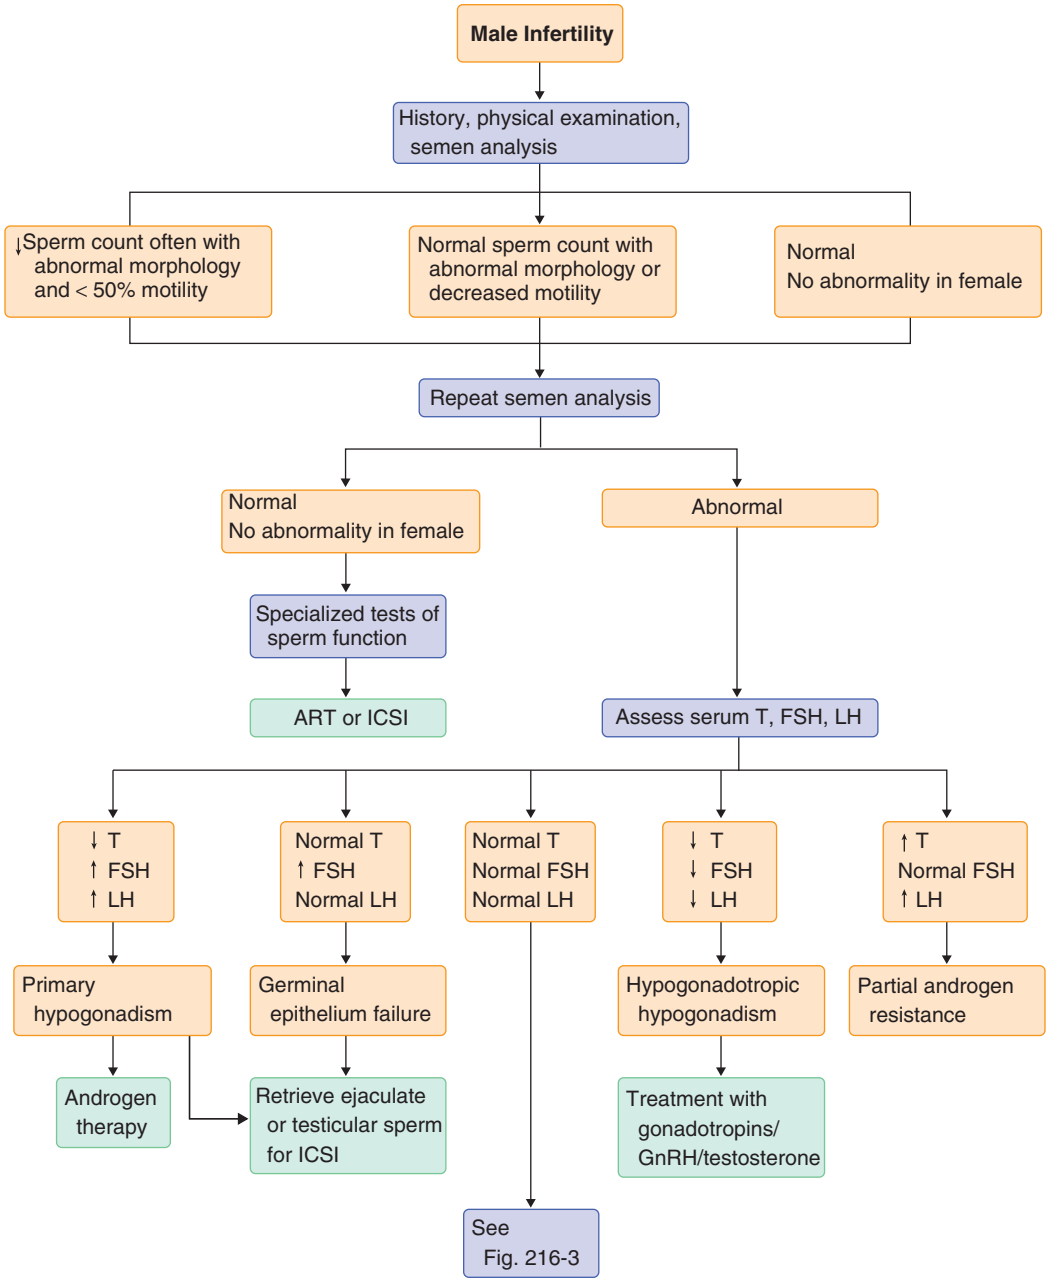


FIGURE 216-2. Algorithmic approach to the diagnosis and treatment of male infertility. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; ICSI = intracytoplasmic sperm injection; LH = luteinizing hormone; T = testosterone.

successful (Chapter 218).[28] Fourth, non-obstructive azoospermia resulting from impaired spermatogenesis may not be a sterile state, because sperm may be present within the testes. Microsurgical testicular sperm extraction from the testis followed by intracytoplasmic sperm injection has good success, even in patients with Klinefelter syndrome. Empirical medical treatments, such as clomiphene citrate, aromatase inhibitors, and recombinant FSH, are not generally recommended because of the paucity of reliable data, although high doses of FSH (700 to 1050 IU per week) can increase sperm concentration and motility.[A11]

SEXUAL DYSFUNCTION

Sexual dysfunction can be divided into four main categories: (1) loss of desire (libido), (2) erectile dysfunction, (3) ejaculatory insufficiency, and (4) anorgasmia. In younger men, the serum testosterone level is associated with sexual desire more than erectile function, but testosterone treatment improves sexual dysfunction in testosterone-deficient men. Total and free testosterone levels have small but statistical associations with sexual desire, erectile function, and sexual activity in symptomatic older men, and treatment with testosterone improves all aspects of sexual function in symptomatic older men with testosterone deficiency (see Table 216-5).

DECREASED LIBIDO

Loss of libido refers to a reduction in sexual interest, initiative, and frequency as well as a diminished response to internal or external erotic stimuli. Causal factors include psychogenic factors, CNS disease, androgen deficiency and resistance, and side effects from medications (e.g., antihypertensive agents, psychotropic agents, alcohol, opiates, dopamine blockers, antiandrogens, and possibly 5α-reductase inhibitors).

A low testosterone level may be the cause of low libido, and a morning level should be obtained. Treatment is directed toward the causal mechanism.

ERECTILE DYSFUNCTION

DEFINITION

Erectile dysfunction can be defined as a man's inability to obtain rigidity sufficient to permit coitus of adequate duration to satisfy himself and his partner.

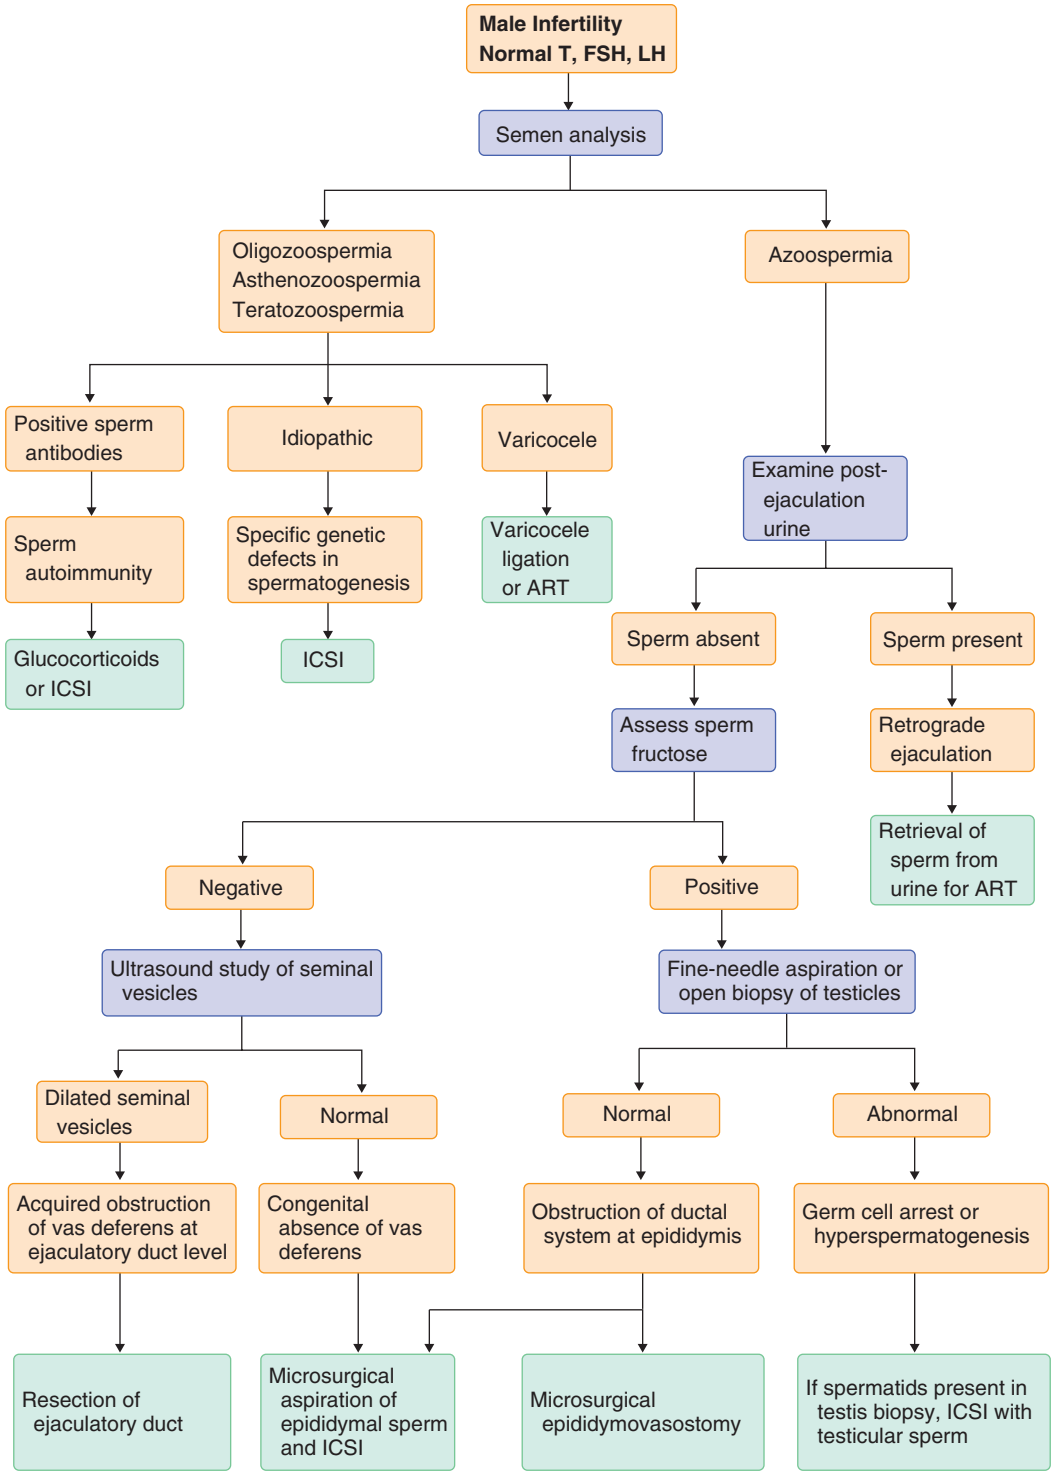

FIGURE 216-3. Algorithmic approach to the diagnosis and treatment of male infertility in patients with normal serum hormone concentrations. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; ICSI = intracytoplasmic sperm injection; LH = luteinizing hormone; T = testosterone.

EPIDEMIOLOGY

Current estimates suggest that 10 to 15% of all adult American men suffer from erectile dysfunction, with the incidence progressively increasing as men become older. In one study, 52% of men ages 40 to 70 years experienced some degree of perceived erectile dysfunction. The prevalence of erectile dysfunction is even higher in men with type 2 diabetes mellitus and after radical prostatectomy for prostate cancer. Epidemiologic studies in the United States and Europe in men between 50 to 80 years indicate that erectile dysfunction is associated with lower urinary tract obstructive symptoms and benign prostatic hyperplasia (Chapter 114).[29] Erectile dysfunction is also associated with increased risks of cardiovascular disease.

PATHOBIOLOGY

The causes of erectile dysfunction are categorized as vasculogenic, psychological, endocrine, neurologic, iatrogenic (post–radical prostatectomy), drug related, systemic illness, and aging. Erectile dysfunction is common in older men, despite normal serum testosterone levels; this effect appears to be the result of impaired penile vasodilatory capacity as a result of endothelial dysfunction. Decreased nonadrenergic, noncholinergic nerve activity, and reduced production of nitric oxide by endothelial cells result in decreased relaxation of cavernous smooth muscle, decreased filling of the cavernous sinusoids, and reduced compression of the venous plexus against the tunica, leading to failure of erection. Men with erectile dysfunction share common risk factors with cardiovascular disease (smoking,

TABLE 216-9 DRUGS COMMONLY ASSOCIATED WITH ERECTILE DYSFUNCTION

ANTIDEPRESSANTS
Selective serotonin reuptake inhibitors Tricyclic antidepressants Monoamine oxidase inhibitors
ANTIHYPERTENSIVES
β-Blockers Verapamil Clonidine
CARDIAC DRUGS
Amiodarone Digoxin
DIURETICS
Thiazides Spironolactone
HISTAMINE RECEPTOR 2 ANTAGONISTS
Cimetidine Ranitidine
HORMONAL AGENTS
Corticosteroids Antiandrogens (flutamide, cyproterone acetate) Luteinizing hormone releasing hormone agonists (leuprolide, goserelin, triptorelin) or antagonists (degarelix, abarelix) 5α-reductase inhibitors (finasteride, dutasteride)

obesity, metabolic syndrome, hyperlipidemia, and type 2 diabetes mellitus), and men with mild erectile dysfunction should be assessed for cardiovascular disease, particularly when other risk factors are present.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis of erectile dysfunction is based mainly on a detailed medical and sexual history of the patient and his partner when available. The history may reveal the underlying cause, such as medication use (Table 216-9), or other common disorders associated with erectile dysfunction. Physical examination should focus on genitourinary, cardiovascular, endocrine, and neurologic systems. Prostate examination is important because erectile dysfunction is commonly associated with symptomatic benign prostatic hyperplasia. Laboratory tests should include a morning serum testosterone level, and, if indicated, prostate-specific antigen, fasting glucose (or hemoglobin A_{1c}), and cholesterol levels. Specific diagnostic tests are rarely required.

TREATMENT

The first goal of treatment is to find any cause and to treat it.[30] Lifestyle interventions to reduce obesity and control glucose levels in patients with type 2 diabetes can improve erectile function.[31]

Medications

Symptoms usually can be effectively treated by the oral administration of a penile-selective phosphodiesterase-5 inhibitor (sildenafil, vardenafil, tadalafil), each of which is effective in about 60% of men.[A12] Patients with diabetes mellitus, spinal cord injuries, prostatic surgery, and pelvic irradiation also benefit, but with a somewhat lower response rate.

The usual starting dose of sildenafil is 50 mg, increasing in 25-mg increments up to 100 mg. Because of its mechanism of action, sildenafil is used on demand with recommended administration 20 to 60 minutes before intercourse. Two other potent phosphodiesterase-5 inhibitors (vardenafil and tadalafil) are widely used for the treatment of erectile dysfunction and appear to be equally effective. Vardenafil (5, 10, and 20 mg) has a relatively longer duration of action (4 to 6 hours), and tadalafil (10 or 20 mg) has an even longer duration of action (up to 36 hours). Randomized controlled trials showed that daily administration of tadalafil (5 mg) improves erectile function compared with on-demand treatment. Daily dosing of tadalafil is well tolerated and effective, so daily dosing, starting with 2.5 mg of tadalafil, may be an alternative to on-demand administration if intercourse is expected to be more frequent—for example, more than twice per week (Fig. 216-4). For patients after radical prostatectomy, early penile rehabilitation with phosphodiesterase type 5 inhibitors contributes to the recovery of erectile dysfunction.[A13]

In patients with a decreased libido and androgen deficiency (a serum testosterone concentration of less than 275 ng/dL and symptoms suggesting testosterone deficiency), sexual function responds moderately well to testosterone gel (see Table 216-5) if no contraindications to testosterone therapy are present. However, the addition of testosterone to sildenafil in partial responders does not further improve erectile dysfunction.

Phosphodiesterase type 5 inhibitors should not be administered with nitrates because the accumulation of cGMP may result in lowering of blood pressure and hypotension. Phosphodiesterase type 5 inhibitors also may interact with antihypertensive agents, including α-blockers, resulting in orthostatic hypotension.

The intraurethral prostaglandin E_1 suppository alprostadil (starting with 125 to 250 μg and increasing to a final dose of 500 to 1000 μg) is thought to work locally on the corpora cavernosa as a vasodilatory agent and is apparently successful in improving erectile function in 30 to 66% of cases. Other medications are under evaluation. For example, in patients with type 2 diabetes, cardiovascular disease, and erectile dysfunction, treatment with dulaglutide (a GLP-1 agonist) has been associated with a reduced incidence of moderate or severe erectile dysfunction.[32] Treatment with L-arginine and low-intensity shock wave therapy in combination with phosphodiesterase type 5 inhibitors also has shown potential efficacy.[33]

Intracavernosal Injection

Second-line treatment of erectile dysfunction involves intracavernosal injection with vasodilators such as prostaglandin E_1 (Alprostadil), either alone or in combination with other vasodilators (papaverine, phentolamine). These medications are injected into the cavernosal space with a 27- to 30-gauge needle in men who are refractory to oral agents. The main side effects of penile injections are pain and cavernosal fibrosis, which usually resolves after discontinuation of injections. Presence of tunica fibrosis may suggest early Peyronie disease, and local injections with vasodilators should be stopped. In such patients, a single intracavernosal injection of botulinum neurotoxin can improve erectile function in about 40 to 50% of patients.[A14]

Penile Prostheses

Surgical implantation of penile prostheses that include semi-rigid (malleable) and inflatable devices are the third line of treatment for men who prefer a permanent solution of their problem or for those who do not respond to other therapies.[34] The protheses and the surgical costs are high, and careful selection

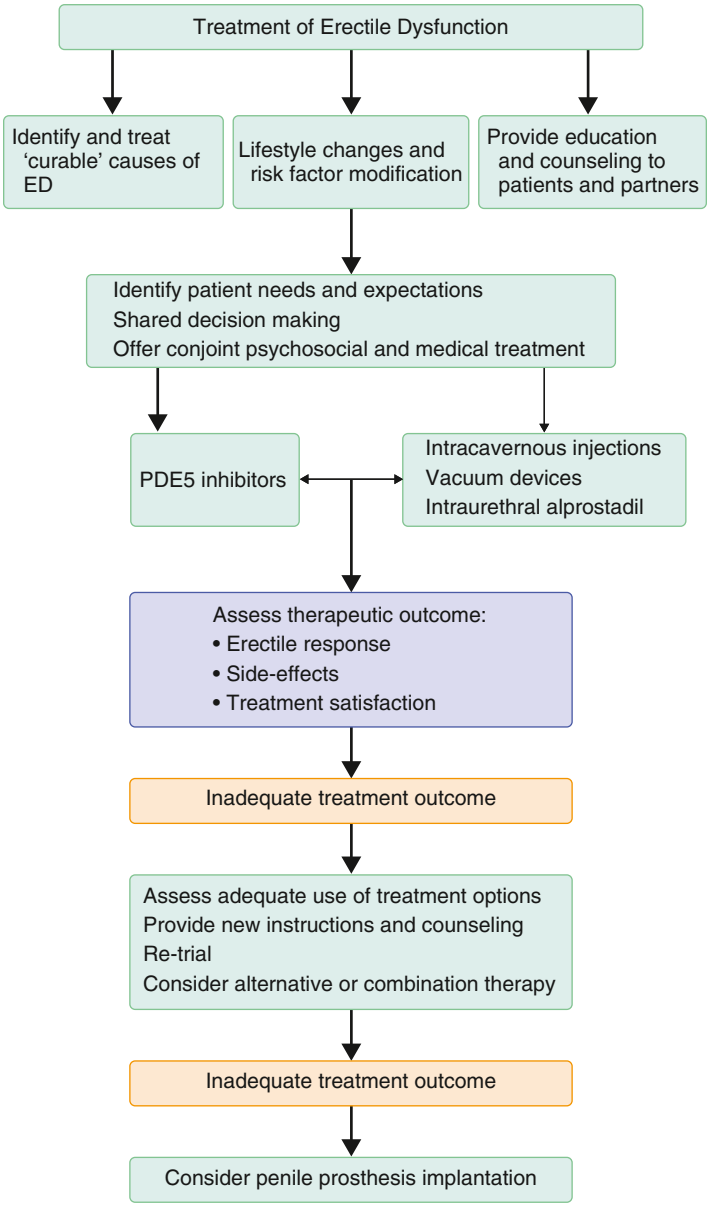

FIGURE 216-4. Treatment algorithm for erectile dysfunction (ED). PDE_5 = cyclic GMP phosphodiesterase 5. (Reprinted with permission from Hatzimouratidis K, Amar E, Eardley I, et al. Guidelines on male sexual dysfunction: erectile dysfunction and premature ejaculation. *Eur Urol*. 2010;57:804-814. 2015 update: http://uroweb.org/guideline/male-sexual-dysfunction/. Accessed March 26, 2015.)

of devices and patients is important for the best outcome. The intraoperative complications include corporal perforations as well as injury to the urethra, bladder, and bowel. Postoperative complications include pain, implant infection, and hematoma. The most common problem with the inflatable implants is mechanical failure in up to 10 to 20% of patients by 10 years. With the proper selection and preoperative preparation of the patient and his partner, long-term data show excellent patient and partner satisfaction.

EJACULATORY FAILURE AND IMPAIRED ORGASM

Ejaculatory insufficiency, which refers to absent or reduced seminal emission or impaired ejaculatory contraction, is usually associated with neurologic conditions and medication therapy. An anorgasmic state, which is a distressing but relatively uncommon condition in men, is characterized by a normal process of erection and ejaculation in the absence of the subjective sensation of pleasure initiated at the time of emission and ejaculation.

Premature ejaculation, which is the most common form of male sexual dysfunction, has a prevalence of 25 to 30%. It is defined as ejaculation occurring within approximately 1 minute of vaginal penetration before the person wishes it to occur on 75% of occasions for at least 6 months, and it associated with personal distress. The pathobiology of premature ejaculation is unknown. It may be associated with marked distress or interpersonal difficulty and is not a direct effect of substance abuse such as opiate withdrawal. The diagnosis is based mainly on sexual history and includes assessment of intravaginal ejaculatory latency time, perceived control, distress, and interpersonal difficulty.

TREATMENT

The first-line treatment for premature ejaculation is selective serotonin reuptake inhibitors (SSRIs; see Table 362-5) or a serotonin transporter inhibitor (e.g., dapoxetine 60 mg or clomipramine 15 mg as on-demand therapy)[A15] together with behavioral therapy and relationship counseling. SSRIs substantially improve symptoms, satisfaction with intercourse, and perceived control over ejaculations. The addition of a phosphodiesterase type 5 inhibitor to a SSRI has better effect than an SSRI alone in prolonging the latency time before ejaculation.[A16] Topical anesthetic creams can be used as alternatives.[A17] Oxytocin antagonists are also being studied for premature ejaculation.

217 OVARIES AND PUBERTAL DEVELOPMENT

WILLIAM H. CATHERINO

DEFINITION

The ovaries or female gonads episodically release female gametes (oocytes or eggs) and secrete sex steroid hormones, principally estradiol and progesterone but also various androgens. Oocytes are released only during the adult reproductive years, when the secretion of sex steroids is also greatest, but the ovaries are physiologically active throughout life.

Sex steroids affect the growth, differentiation, and function of a variety of tissues and organs throughout the body, so abnormalities of the ovaries and of sex steroid secretion should be recognized by all physicians. A rational approach to the diagnosis and treatment of reproductive disorders in women requires an understanding of the functions of the ovaries and of their most important unit, the follicle, throughout life.

PATHOBIOLOGY

Ovarian Function in Childhood and Puberty

Physical Changes at Puberty

Puberty extends from the earliest signs of sexual maturation until the attainment of physical, mental, and emotional maturity. Pubertal changes in girls result directly or indirectly from maturation of the hypothalamic-pituitary-ovarian unit (Chapter 204).[1] Human puberty is characterized hormonally by a resetting of the negative gonadal steroid feedback loop, the establishment of new circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the female of a positive estrogen feedback loop that controls the menstrual cycle as interdependent expressions of the gonadotropins and ovarian steroids. In girls, pubertal development generally occurs between 7 and 14 years of age. The age at onset and the rate of progress through puberty are variable and depend on genetic, socioeconomic, nutritional, physical, and psychological factors. Racial differences also appear to be relevant for the onset of pubertal development. For example, in the United States, pubertal development begins earlier in Black girls than in White girls.

Physical changes occur in an orderly sequence during a definite time frame in puberty (Fig. 217-1). Breast budding in girls is usually the first pubertal change, followed shortly by the appearance of pubic hair, with menarche occurring late in pubertal development. The time from breast budding (mean age of 10.0 years in White girls and 8.9 years in Black girls) to menarche is 2 years. Breast development results from increasing ovarian production of estrogen, and pubic and axillary hair results from increasing androgen production. Estrogens are required for the growth of pubic hair as well.

The ovarian sex steroids join with growth hormone and adrenal androgens to produce the adolescent growth spurt.[2] Peak growth velocity is achieved relatively early, with little growth observed after menarche. Estrogens are necessary for the normal formation, mineralization, and maturation of bones. Estrogen, not testosterone, is the primary hormone that mediates pubertal bone growth in both males and females, and more than 50 genes play roles in determining final adult height. Well-established standards exist for determining whether bone age is appropriate for chronologic age, typically by examining radiographs of the bones of the wrist. Estrogen deficiencies retard, and excesses advance, bone age in relation to chronologic age.

Lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity, women have twice as much body fat as men but have less lean body mass and skeletal mass as a result of differences in sex steroids.

Hormonal Changes

The ovaries function even in early childhood. Levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are normally low, and these levels increase if the ovaries are removed before puberty, just as they do later in life, thereby indicating the exquisite sensitivity of the hypothalamic-pituitary unit to extremely low circulating sex steroid levels. As puberty nears, a progressive decrease in the sensitivity of the hypothalamic-pituitary unit to sex steroids leads to the increased secretion of pituitary gonadotropins, stimulation of sex steroid output, and development of secondary sex characteristics. Increased secretion of both LH and FSH initially occurs at night with sleep and is associated with increased estradiol secretion the next morning (Fig. 217-2). As is true for most hormones, LH and FSH are secreted in an episodic or pulsatile rather than a continuous fashion (Chapter 205). Later in puberty, secretion of LH and FSH is increased throughout the 24-hour period, except during the early follicular phase, when nighttime increases still occur. Basal levels of estradiol, the major estrogen secreted by the ovaries, increase throughout puberty. A "critical body mass" may be required for positive estrogen feedback and ovulation. During the first 2 years after menarche, up to 90% of menstrual cycles may be anovulatory because of a delay in synchronization of the hypothalamic-pituitary-ovarian axis.

Ovarian Cysts and Adnexal Masses

Follicular growth, resulting in an ovarian cyst, is an expected finding during the reproductive years. However, palpable masses before or after the reproductive years require thorough investigation to exclude various cancers (Chapter 184). A pelvic mass during the reproductive years could represent an ovarian cyst, but could also represent an endometrioma, ovarian fibroma, intrauterine pregnancy, ectopic pregnancy (Chapter 218), uterine fibroid (Chapter 184), tubo-ovarian abscess (Chapter 264), peritubal cyst, or less likely, ovarian or tubal cancer.[3] History, physical examination, pregnancy test, and pelvic ultrasound would assist in focusing the differential diagnosis. CA-125 during the reproductive years is nonspecific and should not be used to exclude ovarian cancer (Chapter 184). Incidentally detected adnexal lesions are found in approximately 4 to 5% of women undergoing computed tomography (CT) scan and in 9 to 10% undergoing ultrasound. The overwhelming majority of

ABSTRACT

Pubertal changes in girls result directly or indirectly from maturation of the hypothalamic-pituitary-ovarian axis. Physical changes occur in an orderly sequence during a definite time frame in puberty. Abnormalities of pubertal development fall into four major categories: (1) precocious puberty; (2) delayed (or interrupted) puberty; (3) asynchronous pubertal development; and (4) heterosexual pubertal development (the most common of which is polycystic ovary syndrome). Diagnostic testing and treatment are discussed.

KEYWORDS

pubertal changes
precocious puberty
delayed puberty
asynchronous pubertal development
polycystic ovary syndrome

these masses are benign, and magnetic resonance imaging (MRI) can decrease the rates of resection or oophorectomy for benign lesions.

ABERRATIONS IN PUBERTAL DEVELOPMENT

Abnormalities of pubertal development[4,5] can be divided into four major categories: precocious puberty, delayed (or interrupted puberty), asynchronous pubertal development, and heterosexual pubertal development (Table 217-1).

PRECOCIOUS PUBERTY

DEFINITION

Precocious puberty represents any pubertal changes before age 9 years in Black girls and before 9 years in White, Asian, and Hispanic girls. Precocious development is isosexual when it is common to the phenotypic sex of the individual and heterosexual when the development is characteristic of the opposite sex. True or central precocious puberty is due to premature maturation of the hypothalamic-pituitary axis. In the absence of increased hypothalamic-pituitary activity, precocious pseudopuberty exists.

EPIDEMIOLOGY

The overall incidence of precocious puberty is estimated to be 1 in 5000 to 10,000 children. About 10 times as many girls as boys are affected.

PATHOBIOLOGY

As many as 20% of individuals with true precocious puberty have tumors of the ovaries (Chapter 184) or adrenal glands (Chapter 208) or one of several organic brain diseases, including tuberous sclerosis (Chapter 385), neurofibromatosis (Chapter 385), encephalitis (Chapter 383), meningitis (Chapter 381), vascular malformations (Chapter 377), and hydrocephalus. When precocious development is isosexual, the cause can be central (true precocious puberty) or peripheral, in which case it is considered gonadotropin-releasing hormone (GnRH)–independent precocious puberty or precocious pseudopuberty. Heterosexual precocity in an apparent prepubertal female is almost always due to congenital adrenal hyperplasia or to an androgen-secreting adrenal or ovarian neoplasm. Only rarely must another disorder of sexual differentiation be considered (Chapter 214).

Various clones of cells in the endocrine glands of girls with McCune-Albright syndrome function autonomously with respect to the production of cyclic adenosine monophosphate as a consequence of a mutation within exon 8 of the G protein α–subunit. This same mutation probably accounts for the bone lesions and café au lait hyperpigmentation. Other endocrine cells may be similarly affected and lead to pituitary adenomas (usually secreting growth hormone), hyperthyroidism, and, rarely, adrenal hyperplasia.

Studies on the etiologic causes for precocious puberty are ongoing,[6] but the most consistent genetic correlates are mutations in the Makorin ring finger protein 3 (MKRN3, function unknown), kisspeptin, the kisspeptin receptor, and the Delta-like homolog 1 (DLK1, a kisspeptin regulator). Kisspeptin and its receptor GPR54 are essential regulators of GnRH-induced gonadotropin secretion and pubertal onset. Activation results in stimulation of the HPO axis, and elevated kisspeptin levels are associated with precocious puberty. Additionally, kisspeptin loss-of-function mutations result in normosmic idiopathic hypogonadotropic hypogonadism.

Excessive androgens produced endogenously by abnormal fetal adrenal glands in utero or diffusing across the placenta to the fetus from the mother can virilize the external genitalia and result in female pseudohermaphroditism.

TABLE 217-1 ABERRATIONS OF PUBERTAL DEVELOPMENT

PRECOCIOUS DEVELOPMENT

- Isosexual precocity
  - Incomplete sexual precocity
    - Premature thelarche
    - Premature pubarche
    - Premature adrenarche
  - True (central) precocious puberty
    - Idiopathic (constitutional)
    - Due to central nervous system lesions
    - Primary hypothyroidism
    - Silver-Russell syndrome
  - Precocious pseudopuberty (of peripheral origin)
    - Ovarian neoplasms
    - Adrenal neoplasms
    - Iatrogenic (estrogen-containing preparations)
    - Human chorionic gonadotropin–secreting neoplasms distinct from central nervous system and ovarian tumors
    - McCune-Albright syndrome
- Heterosexual precocity
  - Ovarian neoplasms
  - Adrenal neoplasms
  - Congenital adrenal hyperplasia
  - Other rare disorders of sexual differentiation

DELAYED PUBERTAL DEVELOPMENT*

- Anatomic abnormalities
  - Müllerian agenesis or dysgenesis (Rokitansky-Küster-Hauser syndrome)
  - Distal genital tract obstruction
    - Transverse vaginal septum
    - Imperforate hymen
    - Vaginal agenesis
- Hypergonadotropic hypogonadism (FSH >30-40 mIU/mL)
  - Gonadal dysgenesis
    - With stigmata of Turner syndrome
    - Pure (46,XX or 46,XY)
    - Mixed
  - Ovarian failure with normal ovarian development
    - Genetic disorders
    - Autoimmune disorders
    - Gonadotropin receptor or postreceptor defects (resistant ovary or Savage syndrome)
    - Enzymatic defects (17α-hydroxylase deficiency, galactosemia)
    - Physical causes: irradiation, chemotherapeutic agents, viral agents
    - Idiopathic
- Hypogonadotropic or normogonadotropic hypogonadism (LH and FSH <10 mIU/mL, or LH and FSH 6-25 mIU/mL with at least one being >10 mIU/mL)
  - Isolated gonadotropin deficiency
    - In association with midline defects (Kallmann syndrome)
    - Independent of associated disorders
  - Neoplasms of the hypothalamic-pituitary axis
    - Craniopharyngiomas
    - Pituitary tumors
    - Others
  - Infiltrative processes (Langerhans-type histiocytosis)
  - Idiopathic hypopituitarism
  - "Hypothalamic" forms of amenorrhea
    - Psychogenic
    - Exercise associated
    - Associated with malnutrition
    - Anorexia nervosa
  - Miscellaneous disorders
    - Prader-Labhart-Willi syndrome
    - Laurence-Moon-Bardet-Biedl syndrome
    - Primary hypothyroidism
  - Constitutional delayed puberty

ASYNCHRONOUS PUBERTAL DEVELOPMENT

- Incomplete forms of androgen insensitivity
- Complete forms of androgen insensitivity

HETEROSEXUAL PUBERTAL DEVELOPMENT

- Polycystic ovary syndrome
- Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - 21-Hydroxylase deficiency
  - 11β-Hydroxylase deficiency
  - 3β-ol-Hydroxysteroid dehydrogenase deficiency
- Male pseudohermaphroditism due to 5α-reductase deficiency
- Male pseudohermaphroditism due to partial androgen insensitivity
- Mixed gonadal dysgenesis
- Androgen-producing neoplasms
  - Ovarian
  - Adrenal
- Cushing syndrome

*No development by age 13 yr, absence of menarche by age 15 yr, or passage of ≥5 yr from breast budding without menarche.
FSH = follicle-stimulating hormone; LH = luteinizing hormone.

CLINICAL MANIFESTATIONS

The temporal sequence in which the signs and symptoms of sex steroid hormone excess appear is most important.[7] Incomplete isosexual precocious puberty indicates premature development of only a single pubertal feature. If breast budding occurs before age 8 years in the absence of any other development, the diagnosis may be premature thelarche. Premature thelarche is believed to be due to transient increases in the secretion of estrogen or increased breast sensitivity to the small quantities of circulating estrogens present before puberty. Simple ovarian cysts may be present in some girls with this disorder and may be due in some cases to the same genetic abnormality found in girls with McCune-Albright syndrome (Chapters 205 and 229). If pubic or axillary hair develops alone and persists, premature pubarche and adrenarche must be considered. These abnormalities are associated with slight increases in adrenal androgen secretion but not with clitorimegaly or other signs of virilization.

DIAGNOSIS

The nearer pubertal development begins to the mean age of the onset of puberty, the less likely it is to have a pathologic basis. Some clinicians believe evaluation is warranted only if pubertal development begins before age 7 years in White girls and 6 years in Black girls. A compromise may involve careful screening by history and physical examination of girls with early-onset puberty, looking for central nervous system (CNS) symptoms, behavioral concerns, and any other abnormal findings that might warrant further evaluation. Careful questioning of the patient and her parents may indicate the inadvertent ingestion or absorption of sex steroids (iatrogenic or factitious). The physical examination may also provide critical information about the cause of the precocious development. Cutaneous café au lait spots, facial asymmetry, polyostotic fibrous dysplasia and other skeletal abnormalities, cranial nerve deficits, and multiple ovarian follicular cysts suggest McCune-Albright syndrome (Chapters 205 and 229) in a girl with precocious development.

Abdominal and rectal examination may reveal a mass, thereby suggesting an adrenal or ovarian tumor. Because palpable ovarian cysts may rarely develop before ovulation in true precocious puberty, the presence of a mass does not confirm the diagnosis of precocious pseudopuberty.

When vaginal bleeding is the only sign of development, the diagnosis of sexual precocity should be suspect. Common causes of bleeding in this age group include irritation from a vaginal infection or foreign body, sexual assault, prolapse of the urethral meatus, and ingestion of estrogen-containing medications (most commonly, oral contraceptive preparations). A vaginal or cervical neoplasm is also a rare possibility. Thus vaginal bleeding requires a vaginal examination, which is often best performed with the patient under anesthesia, before further evaluation is undertaken.

It is important to examine the external genitalia carefully, because congenital adrenal hyperplasia is usually associated with some degree of sexual ambiguity. In female pseudohermaphroditism, the extent of virilization varies from only an enlarged clitoris to sexual ambiguity sufficient to make gender assignment difficult.

Excessive maternal androgen secretion, typically from an ovarian or adrenal neoplasm, can lead to virilization of a female fetus. This abnormality occurs very rarely because of the great capacity of the placenta to aromatize naturally occurring androgens to estrogens. Virilization of a female fetus is much more likely to occur if a pregnant woman has ingested a synthetic steroid preparation with androgenic properties, because synthetic compounds generally cannot be aromatized.

Excessive androgen secretion beginning in utero is usually associated with defective cortisol synthesis. As a consequence, pituitary corticotropin secretion is increased, thereby resulting in congenital adrenal hyperplasia and excessive androgen secretion. The three different enzyme defects in the steroidogenic pathway that can lead to virilization of the female fetus are described in Chapter 214. The most common form of congenital adrenal hyperplasia is 21-hydroxylase deficiency, which accounts for the disorder in more than 90% of affected individuals. The defect may vary from partial to complete deficiency of the enzyme.

Diagnostic Tests

The evaluation begins by obtaining blood levels of FSH, LH, estradiol, human chorionic gonadotropin, and thyroid-stimulating hormone.[8] Additional testing may involve a bone age, brain MRI, ultrasound of the abdomen and pelvis, and a 17-hydroxyprogesterone level.

Measurement of Peptide and Steroid Hormones

Levels and ratios of FSH and LH typical of pubertal as opposed to prepubertal girls help in the diagnosis of true precocious puberty. Excessively high circulating levels of estrogen (>100 pg/mL estradiol) suggest an estrogen-producing neoplasm or a functioning ovarian cyst. High levels of serum testosterone suggest an ovarian source of excess androgen in girls with heterosexual development, whereas increased levels of dehydroepiandrosterone or its sulfate (the principal precursors of 17-ketosteroids) suggest an adrenal source. High levels of serum 17-hydroxyprogesterone imply congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, whereas high levels of serum 11-deoxycortisol imply an 11β-hydroxylase deficiency (Chapter 214). In congenital adrenal hyperplasia, these hormone levels should decrease promptly after the oral administration of suppressive doses of dexamethasone. Suppression in response to exogenous corticoids occurs much less consistently in individuals with adrenal cortical adenomas and carcinomas (Chapter 208) and rarely in those with ovarian androgen-secreting neoplasms. Increased levels of immunoreactive human chorionic gonadotropin (HCG) may suggest an HCG-secreting neoplasm, most commonly an ovarian teratoma or dysgerminoma. In such cases, the HCG, which is antigenically and biologically similar to LH, stimulates ovarian steroid secretion and pseudopubertal development. Because even specific LH immunoassays show some cross-reactivity with HCG, values for serum LH may be elevated in individuals with HCG-secreting tumors. Immunoreactive HCG is always elevated in the presence of such tumors.

Administration of an exogenous GnRH agonist to stimulate endogenous LH secretion is useful, with an LH level >5 mIU/mL as confirmation of gonadotropin-dependent disease rather than gonadotropin-independent disease. Furthermore, an LH/FSH ratio >0.66 can be used to distinguish progressive from nonprogressive precocious puberty. This test is regarded as the "gold standard" for the diagnosis of central precocious puberty related to the hypothalamic-pituitary-ovarian axis.[9]

Additional Studies

Imaging of the CNS is the most important test if true central precocious puberty is present or if there are any neurologic deficits. Because of the seriousness of intracranial lesions, girls with precocious puberty must have radiographic evaluation of the CNS, most effectively by MRI. At least 75% of girls with true precocious puberty, however, have precocious puberty with no specific idiopathic or constitutional cause identified.

Ultrasonography of the adrenals and ovaries or computed tomography (CT) of the adrenals may be indicated to confirm clinically suspected abnormalities based on endocrine testing. In girls with ovarian or adrenal neoplasms, the tumor can almost always be localized radiographically. Catheterization of the ovarian and adrenal veins and measurements of the effluent steroids from each gland should be pursued only when CT, ultrasonography, or MRI fails to identify a suspected neoplasm.

Radiographic estimation of bone age is also routinely indicated. The results serve as a useful baseline to assess the results of treatment.

TREATMENT

Premature pubarche and adrenarche without puberty require no treatment, and affected girls typically begin true puberty at the usual age. Careful follow-up is required to distinguish these disorders from true precocious puberty.

Treatment of precocious puberty (Table 217-2) should be initiated promptly so that the patient's ultimate height is not compromised as a result of sex steroid–induced premature epiphyseal closure. Prompt treatment also can prevent or attenuate emotional consequences in the patient and her parents.[10,11]

In girls who present before age 6 years with central precocious puberty, GnRH analogues (see Table 217-2), which are now the preferred therapy for suppressing gonadotropin secretion, may prevent early bone maturation and increase ultimate adult height. The preferred duration of treatment is uncertain and should be tailored to patient goals.

In girls who are between 6 and 8 years of age, the indications for treatment are less clear. Some data suggest that antiandrogens (e.g., spironolactone 50 to 200 mg every other day) or oral contraceptive pills (Table 220-2) in combination with metformin (500 to 2000 mg daily) may improve hirsutism and oligomenorrhea in the teenage years.[12] These analogues are not effective in children with McCune-Albright syndrome, in whom aromatase inhibitors (e.g., letrozole 2.5 mg daily) show promise. Aqueous depot medroxyprogesterone acetate (100 to 200 mg intramuscularly every 2 to 4 weeks) also may be used to suppress gonadotropin secretion. It does not always prevent premature epiphyseal closure and the resultant short stature, but it may be helpful in regulating disrupted menses.

Individuals with CNS or steroid-secreting neoplasms must undergo therapy appropriate for the particular lesion. Girls with congenital adrenal hyperplasia are appropriately managed with glucocorticoids (plus mineralocorticoids when indicated), as outlined in Chapter 214.

DELAYED PUBERTY

Delayed (or interrupted) puberty is defined as the absence of any secondary sex characteristics by age 13 years, the absence of menarche by age 16 years, or the passage of 5 years or more from breast budding to menarche.[13] More than 50% of cases represent constitutional delay and resolve spontaneously.

TABLE 217-2 TREATMENT OF PRECOCIOUS PUBERTY

CENTRAL PRECOCIOUS PUBERTY
Treatment Time 1 month: 0.2-0.3 mg/kg leuprolide acetate IM 3 months: 11.25-30 mg leuprolide acetate IM 6 months: 45 mg leuprolide acetate SQ 6 months: 22.5 mg triptorelin acetate IM 12 months: 50 mg histrelin implant SQ
PERIPHERAL PRECOCIOUS PUBERTY
Letrozole 2.5 mg/day as first line, follow-up with endocrinologist

IM = intramuscularly; SQ = subcutaneously.

PATHOBIOLOGY

Ovarian failure, congenital absence of the uterus and vagina, and constitutional delay, or delayed but otherwise normal progression through puberty, constitute about two thirds of cases in large series. Congenital malformations of the müllerian ducts occur in 0.02% of all women. Most do not cause amenorrhea, and many do not impair reproduction. The anomalies associated with amenorrhea vary in severity from an imperforate hymen to complete aplasia of all müllerian duct derivatives, with vaginal atresia. Although aplasia generally involves all the müllerian duct derivatives, defects may involve only a single part of the distal genital tract. Family aggregates of the most common disorders of müllerian differentiation in females—müllerian aplasia and incomplete müllerian fusion—do occur and are best explained by polygenic or multifactorial inheritance. The *HOX* genes, a family of regulatory genes that encode transcription factors, are essential for proper development of the müllerian tract.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Because of the anxiety generated by delayed puberty, some evaluation is always indicated regardless of the age of the patient.

To evaluate delayed puberty, initial studies include FSH, LH, and estradiol levels. Primary ovarian failure is diagnosed if the FSH level is >20 mIU/mL.

When pubertal development progresses normally but menstruation does not begin, an abnormality in the genital tract should be considered. A müllerian duct anomaly is suggested by (1) normal levels of serum gonadotropins and steroids, (2) an abnormal outflow tract, (3) a history of cyclic abdominal pain with or without a palpable mass, and (4) normal development of secondary sex characteristics. Normal ovarian function still induces endometrial growth and shedding after menarche if the uterus is normal. In the absence of a normal outflow tract, however, the menstrual effluent is retained and may or may not escape into the abdominal cavity. Free in the abdominal cavity, the effluent may cause endometriosis. Constrained to the uterine cavity, the effluent causes hematometra and a large abdominal mass.

In the absence of a mass or cyclic pain, karyotyping is indicated in girls with evidence of an abnormal genital tract to exclude disorders of sexual differentiation (Chapter 214).[14] Such disorders, however, almost never occur together with completely normal pubertal development. In girls with a normal karyotype and a genital tract anomaly, examination under anesthesia and diagnostic laparoscopy should be undertaken to delineate the extent of the defect.

Other causes of delayed puberty and primary amenorrhea are the same as those that cause amenorrhea in older women (Chapter 218).[15] When no apparent cause of delayed development is found, constitutional delayed puberty must be entertained as a diagnosis of exclusion. A strong family history of delayed maturation supports this presumption.

TREATMENT

For constitutional delayed puberty, small doses of estrogen (starting with 5 µg of ethinyl estradiol or 0.3 mg of conjugated estrogen) can be administered to induce some pubertal development based upon the patient's wishes. However, this treatment may obscure a pathologic cause of the delay and may compromise linear growth and ultimate height.

In patients with an imperforate hymen or transverse vaginal septum only, surgical restoration can be accomplished relatively simply. Attempts to provide an outflow tract for the uterus should not be undertaken if there is no cervix because of the high risk of recurrent pelvic infection. Even with a functional cervix, the construction of an outflow tract that permits successful pregnancy is unlikely. A functional vagina can be constructed surgically or by the daily use of ever-larger dilators. To prevent shrinkage and scarring, surgery should be deferred until the patient is willing to use dilators on a daily basis or she is about to become sexually active.

ASYNCHRONOUS PUBERTAL DEVELOPMENT

Asynchronous pubertal development occurs when there is deviation from the normal pattern of pubertal development. Asynchronous pubertal development is characteristic of male pseudohermaphroditism due to androgen insensitivity, especially complete testicular feminization. This syndrome of androgen insensitivity is inherited as either an X-linked recessive trait or a sex-limited autosomal dominant trait. Despite the presence of intra-abdominal or inguinal testes, there is complete failure of virilization. Affected individuals develop breasts (but only to Tanner stage 3) and a typical female habitus with unambiguous female external genitalia, but with the absence of internal female structures and generally only a foreshortened, blind-ending vagina. Little or no pubic and axillary hair develops. The karyotype is 46,XY in these individuals. Circulating testosterone levels are equivalent to or higher than those found in normal men, LH levels are elevated, and FSH levels are normal compared with those in menstruating women. For a more detailed description, see Chapter 214.

HETEROSEXUAL PUBERTAL DEVELOPMENT

Heterosexual pubertal development occurs at the appropriate time but has some features characteristic of the opposite sex.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS), which is by far the most common cause of heterosexual pubertal development, is associated with the development of some secondary sex features characteristic of males at the normal age of puberty.[16] Many girls who develop PCOS have alterations in insulin signaling.

Feminization occurs in affected girls, who develop normal breasts and a typical female habitus but also have features of masculinization (in contrast, girls with congenital adrenal hyperplasia generally show little, if any, female development at puberty). A heterogeneous syndrome, PCOS typically begins at or near puberty with hirsutism and irregular menses from the time of menarche. Many girls who develop PCOS are overweight in childhood, and obesity worsens the phenotype. Menarche may be delayed in a few cases, so young women may present with primary amenorrhea. Basal LH levels tend to be somewhat elevated in perhaps two thirds of cases, and circulating levels of all androgens are moderately elevated.[17] Some degree of insulin resistance is commonly present as well, and hypercholesterolemia may predispose to cardiovascular disease later in life. PCOS is discussed more completely in Chapter 218.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia is generally diagnosed before puberty. Heterosexual precocious pseudopuberty or phenotypical androgenization due to adrenal tumors in females is common.[18] However, if the defect is mild and changes to the external genitalia are minimal, masculinization may occur at the expected age of puberty. This attenuated or nonclassic form of 21-hydroxylase deficiency seems to occur in families with a strong history of hirsutism. Affected girls generally have some defeminization, with flattening of the breasts, severe hirsutism, relatively short stature, and obesity. For a more detailed description, see Chapter 214.

MIXED GONADAL DYSGENESIS

Mixed gonadal dysgenesis is a rare disorder of asymmetrical gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other. Affected individuals generally have a mosaic karyotype, with 45,X/46,XY being the most common.

The clinical presentation varies based upon chromosomal alterations.[19] Most individuals are reared as girls, in whom virilization occurs at puberty; some may note breast development as well. Short stature and other stigmata associated with a 45,X karyotype in Turner syndrome are less common in patients with tumors than in patients with testes. Gonadectomy is indicated in all individuals with a Y chromosome to eliminate the increased neoplastic potential of such dysgenetic gonads and in all patients in whom virilization occurs at puberty to remove the source of androgen. Estrogen replacement therapy (ethinyl estradiol 5 µg daily or conjugated estrogen 0.3 mg daily to start) is warranted after gonadectomy. Other causes of male pseudohermaphroditism associated with heterosexual pubertal development are described in Chapter 214.

OTHER CAUSES

An androgen-producing adrenal neoplasm or Cushing syndrome (Chapter 208) may occur rarely during the pubertal years and lead to heterosexual development.

218 REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY

WILLIAM H. CATHERINO

THE NORMAL MENSTRUAL CYCLE

Endometrium

The endometrium undergoes histologic and cytologic changes that culminate with menstrual bleeding when the corpus luteum ceases to secrete progesterone (Fig. 218-1). The basal layer of the endometrium then regenerates the superficial layer of compact epithelial cells that line the uterine cavity and an intermediate layer of spongiosa. Endometrial glands proliferate under the influence of estrogen, and the mucosa thickens. In the luteal phase, the glands become coiled and secretory, with increased vascularity and edema of the stroma. When estradiol and progesterone decline, the stroma becomes edematous, endometrial and blood vessel necrosis occurs, both the superficial epithelial cells and the spongiosa are shed, and bleeding ensues. Local release of prostaglandins may initiate vasospasm, which results in ischemic necrosis, as well as the uterine contractions that accompany menstrual flow. Prostaglandin synthetase inhibitors can relieve menstrual cramping. The histologic changes are characteristic, so endometrial biopsies can identify the stage of the cycle and assess the endometrium's response to gonadal steroids.

Cervix and Cervical Mucus

During the follicular phase, cervical vascularity, congestion, and edema increase as a result of estrogen. Cervical mucus increases in quantity (10- to 30-fold) and in elasticity. So-called ferning becomes prominent. Progesterone stimulates the thickening of cervical mucus, the loss of elasticity, and loss of the ability to fern.

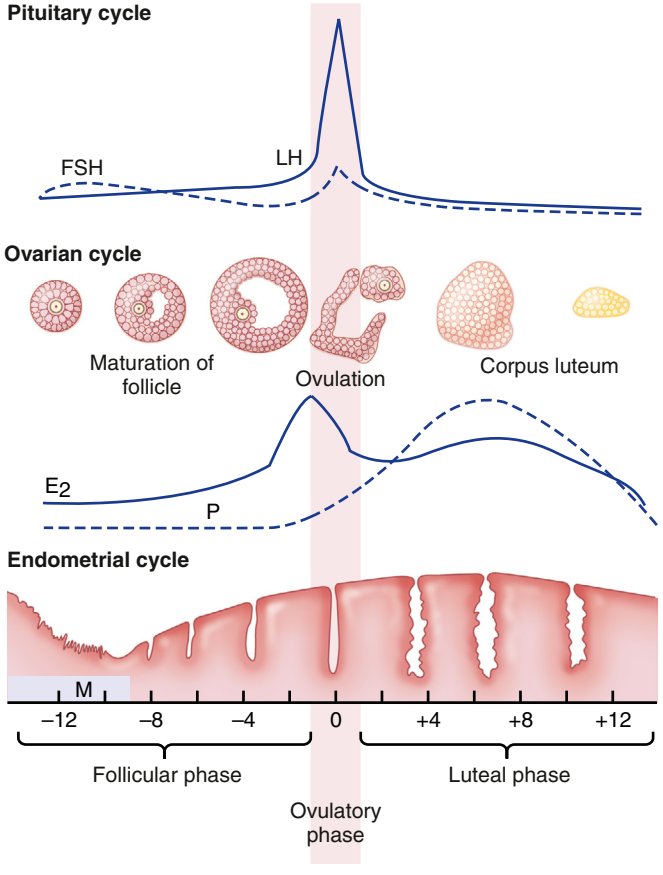

FIGURE 218-1. **The idealized cyclic changes observed in gonadotropins, estradiol (E_2), progesterone (P), and uterine endometrium during the normal menstrual cycle. The data are centered on the day of the luteinizing hormone (LH) surge (day 0). Days of menstrual bleeding are indicated by M. FSH = follicle-stimulating hormone; LH = luteinizing hormone. (From Endocrine and Metabolism Continuing Education Quality Control Program, 1982. Copyright American Association for Clinical Chemistry, Inc.)**

Vagina

Low estrogen is associated with pale, thin vaginal epithelium. As estrogens rise, the number of cornified epithelial cells increases. Subsequently, progesterone decreases the percentage of cornified cells and increases the number of precornified intermediate cells, thereby resulting in increased cellular debris and clumping of shed desquamated cells. Histologic changes in the vaginal epithelium are sensitive indicators of estrogen status.

Ovary

The ovaries produce a single dominant graafian follicle that grows and develops to the preovulatory stage during the follicular phase. This process is brought about by combined action of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) on the granulosa cells that comprise the follicle wall to increase estradiol biosynthesis. The LH surge acts on the preovulatory follicle to cause the secretion of the mature fertilizable oocyte. After ovulation, the follicle wall transforms into the corpus luteum, which produces progesterone and estradiol. If implantation does not occur, the corpus luteum undergoes luteolysis and stops hormone production. In the late luteal phase, another dominant follicle develops, and a new menstrual cycle begins.

Chronology of Folliculogenesis

The preovulatory follicle begins its development when a primordial follicle is recruited into the pool of growing follicles. The two major phases of folliculogenesis are the preantral (gonadotropin-independent) and the antral (gonadotropin-dependent) phases (see Fig. 218-1). The first phase is characterized by growth of the oocyte and proliferation of the granulosa cells. Preantral folliculogenesis, which proceeds slowly, requires at least 300 days. During the second phase, granulosa and theca cells proliferate, and the antrum enlarges. The graafian follicle increases relatively rapidly as it develops. The mature graafian follicle that will ovulate requires 40 to 50 days to complete the antral phase.

Selection

The dominant follicle is selected from a cohort at the end of the luteal phase of the previous menstrual cycle. The selected follicle requires 20 days to develop to the ovulatory stage.

Shortly after the midluteal phase of the cycle, the granulosa cells show a sharp increase in the rate of mitosis. The first indication of selection is that the granulosa cells continue dividing at a high rate. As a consequence of the high sustained mitotic rate and the progressive accumulation of follicular fluid, the dominant follicle undergoes remarkable growth. The increase in plasma FSH levels that begins at the end of luteal phase and continues through the early follicular phase evokes follicle selection. The concentration of FSH in the follicular fluid of the healthy (dominant) follicle increases but does not increase in the nondominant atretic follicles. More than 99.9% of all follicles are not selected and undergo atresia.

Ovulation

At midpoint in the menstrual cycle, the preovulatory surges of LH and FSH act on the preovulatory follicle to initiate the events leading to ovulation (see Fig. 218-1). The LH surge induces meiotic maturation, a process that converts the oocyte into a fertilizable egg arrested at the second meiotic metaphase. During meiotic maturation, the granulosa cells next to the oocyte are stimulated by FSH to undergo cumulus expansion (Fig. 218-2). This step is a prerequisite for the oocyte's pickup and transport by the oviduct. The LH surge also stimulates production of proteolytic enzymes in the vicinity of the presumptive stigma. This process requires the LH stimulation of progesterone and prostaglandins, which are obligatory for stigma formation. After 36 hours, the fertilizable egg and surrounding cumulus cells are secreted through the stigma (see Fig. 218-1). A serum progesterone level higher than 3 ng/mL at 1 week before menses is probably diagnostic of ovulation.

Luteogenesis

Ovulation changes the granulosa and theca cells of the ovulated follicle to increase their production of progesterone and estradiol during the first week of the luteal phase. This event, termed *luteinization*, is important for the formation and development of a secretory endometrium. Three major

ABSTRACT

With an understanding of the biologic basis of the normal menstrual cycle, the diagnosis and management of abnormalities during the reproductive years can be addressed. Dysmenorrhea, endometriosis, premenstrual syndrome, abnormal uterine bleeding, and sexual dysfunction are common clinical syndromes that must be approached systematically. Amenorrhea can be due to anatomic factors (disorders of sexual differentiation, intrauterine adhesions, gestational trophoblastic disease), chronic anovulation (CNS-hypothalamic-pituitary dysfunction, inappropriate steroid feedback as in polycystic ovary syndrome, thyroid or adrenal disorders), or ovarian "failure" (menopause, genetic abnormalities, physical and environmental factors, autoimmune disease). Multiple male factors and female factors can cause infertility.

physiologic mechanisms are responsible for luteinization: removal of luteinization inhibitors, secretion of LH by the pituitary, and delivery of high levels of cholesterol. The induction of steroidogenic acute regulatory protein StAR, P450c22, and 3β-hydroxysteroid dehydrogenase in the granulosa lutein cells leads to the production of progesterone by the corpus luteum. The two-cell, two-gonadotropin mechanism is responsible for the production of estradiol. If implantation does not occur, the corpus luteum initiates luteolysis, thereby decreasing progesterone and estradiol and resulting in apoptosis. When luteolysis occurs, another dominant follicle is selected, and a new menstrual cycle begins.

MENSTRUAL SYMPTOMS

DYSMENORRHEA AND ENDOMETRIOSIS

Dysmenorrhea, defined as painful menstruation, affects about 50% of postpubertal women and can be classified as primary or secondary. Endometriosis, which affects about 10% of women of reproductive age, is the ectopic presence of endometrial tissue (glands and stroma), most commonly within the abdominal cavity but sometimes in surgical scars, on the vulva, in the umbilicus, and elsewhere.[1] Endometriosis may result in dysmenorrhea, infertility, and dyspareunia (i.e., painful intercourse).

Primary dysmenorrhea usually, but not always, occurs in ovulatory cycles.[2] Prostaglandins produce dysmenorrhea by initiating painful, exaggerated uterine contractions and myometrial ischemia. Associated systemic symptoms include nausea, diarrhea, headache, and emotional changes. By comparison, secondary dysmenorrhea has a pathologic cause, with endometriosis being the most common.[3] Other causes include pelvic inflammatory disease (Chapter 264); congenital abnormalities, such as atresia of a portion of the distal genital tract and cystic duplication of the paramesonephric ducts; and cervical stenosis.

TREATMENT AND PROGNOSIS

To treat primary dysmenorrhea, over-the-counter nonsteroidal anti-inflammatory drugs (NSAIDs), which inhibit prostaglandin synthase (e.g., naproxen, ibuprofen, or prescription NSAIDs such as mefenamic acid, piroxicam, diclofenac, and meclofenamate), should be started as soon as bleeding or cramping begins and continued for up to 3 days (Table 218-1).[4] NSAIDs should not be used in women who cannot maintain adequate hydration; have underlying renal disease; are receiving anticoagulants, systemic glucocorticoids, lithium, or loop diuretics; or have a history of gastrointestinal bleeding, coagulopathy, ischemic heart disease, stroke, heart failure, liver disease, or aspirin-sensitive asthma. If the dysmenorrhea persists, addition of an oral contraceptive to inhibit ovulation and limit the release of prostaglandin is generally effective. If the pelvic pain remains intractable, additional evaluation is warranted. If thorough evaluation of the gastrointestinal and urinary tracts fails to reveal a definitive cause, examination under anesthesia and diagnostic laparoscopy may be indicated.

If endometriosis is diagnosed at laparoscopy, treatment varies according to the severity of the disease and the patient's goals regarding fertility.[5,6] Initial options include fulguration or excision of implants with lysis of adhesions. Persistent endometriosis can be treated medically, with additional surgery deferred should medical therapy fail. Medical therapy can consist of continuous suppression with oral contraceptives,[A1] progestins (e.g., norethindrone 5 mg daily),[A2] gonadotropin-releasing hormone (GnRH) analogues (e.g., leuprorelin 3.75 or 11.25 mg subcutaneously monthly), a GnRH receptor antagonist (elagolix 150 mg orally daily for up to 24 months[A3] or relugolix 40 mg orally daily),[A4] or danazol for 3 to 6 months.[A3] After a course of treatment, use of oral contraceptive agents should probably be continued until fertility is desired. Conservative surgical resection of endometriotic tissue should almost always be deferred until it is established as the cause of infertility. Surgery may be required, however, for continuing severe pain, severe endometriosis, or large ovarian cysts containing endometriosis (endometriomas).

Some patients have chronic pelvic pain that persists for more than 6 months, often related to menses or intercourse.[6,7] The cause is unknown, but patients often have coexisting fibromyalgia (Chapter 253) or migraine headaches (Chapter 367). If symptoms continue, medical causes have been excluded, or psychological overlay is suspected, multimodality psychosocial intervention or psychiatric evaluation may be indicated.

TABLE 218-1 SUGGESTED ORAL NONSTEROIDAL ANTI-INFLAMMATORY DRUGS TO INHIBIT PROSTAGLANDIN SYNTHASE IN PRIMARY DYSMENORRHEA

DRUG	INITIAL DOSE	SUBSEQUENT DOSING OVER 3 DAYS IF NEEDED
Naproxen sodium	550 mg	275 mg every 6 to 8 hours up to 1375 mg total
Ibuprofen	400 to 800 mg	400 to 800 mg every 4 to 6 hours up to 2400 mg total
Mefenamic acid	500 mg	250 mg every 6 hours up to 1000 mg
Piroxicam	20 mg	10 mg to a total dose of 20 mg once daily
Diclofenac	75 to 100 mg	50 mg every 8 hours to a total dose of 150 mg
Meclofenamate	100 mg	50 mg every 4 to 6 hours up to 400 mg total

PROGNOSIS

With effective treatment, quality of life improves significantly. Should initial therapy fail, however, referral to a reproductive endocrinologist is warranted.

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS), also known as premenstrual tension, is a complex of physical and emotional symptoms that occur repetitively in a cyclic fashion before menstruation and that diminish or disappear with menstruation. About 50% of menstruating women have symptoms of varying severity.

The cyclic symptoms typically are sufficiently severe to interfere with some aspects of life. More than 150 different symptoms are now thought to vary with the menstrual cycle (Table 218-2). Estimates of the prevalence of premenstrual syndrome range from 25 to 100%. For most women, premenstrual syndrome is merely annoying, but severe premenstrual syndrome causes serious difficulties for 3 to 5% of women of reproductive age.

Most women seek help for premenstrual syndrome in their 30s after 10 or more years of symptoms. Many report that their symptoms began at menarche; approximately half state that symptoms followed childbirth. Severity and duration of symptoms are often reported to increase after each successive pregnancy and to become more severe with advancing age. Women with severe

TABLE 218-2 COMMON SYMPTOMS OF CYCLIC PREMENSTRUAL SYNDROME

SOMATIC SYMPTOMS	
Abdominal bloating	Constipation or diarrhea
Acne	Headache
Alcohol intolerance	Peripheral edema
Breast engorgement and tenderness	Weight gain
Clumsiness	
EMOTIONAL AND MENTAL SYMPTOMS	
Anxiety	Insomnia
Change in libido	Irritability
Depression	Lethargy
Fatigue	Mood swings
Food cravings (especially salt and sugar)	Panic attacks
Hostility	Paranoia
Inability to concentrate	Violence toward self and others
Increased appetite	Withdrawal from others

long-standing premenstrual syndrome almost always describe associated psychological reactions, including social difficulties such as marital discord, difficulty relating to their children, difficulty maintaining friendships, and withdrawal from social activities.

The diagnosis is best established by requiring affected individuals to keep prospective daily records of symptoms during a 2- to 3-month period. Less than 50% of women who complain of premenstrual syndrome are found to have the syndrome when such records are examined.

TREATMENT

General Measures

The cause of premenstrual syndrome is unknown, and patients should be informed that no one therapy has been effective in all women. Women with mild premenstrual symptoms often benefit from simple changes in lifestyle, including daily mild aerobic exercise; reduction in intake of caffeine-containing beverages, salt, and refined sugar, particularly in the luteal phase; stress reduction; and adequate rest.

Medical Therapy

Women with more severe premenstrual syndrome may benefit from symptomatic treatment.[8] Continuous oral contraceptives (see Table 220-3) have inconsistent but generally positive therapeutic benefit, although intermittent drospirenone/ethinyl estradiol (3 mg/20 µg) dosed on a 21-7 schedule (21 active pills followed by 7 placebo pills) has comparable efficacy to the continuous combined oral contraceptives.[A5] Off-label bromocriptine (generally 2.5 mg twice a day) or danazol (100 to 400 mg/day in two divided doses) may be given continuously for relief of mastalgia (breast pain), although its efficacy has not been documented by rigorous randomized trials. NSAIDs (see Table 218-1) may help reduce pain and alleviate headaches. Mild sedatives and anti-anxiety drugs (Table 362-9) may help reduce insomnia and anxiety. For example, low doses of fluoxetine (10 to 20 mg) and other selective serotonin re-uptake inhibitors (Table 362-5), administered either daily or for the last 2 weeks of each menstrual cycle, are highly effective in reducing the emotional symptoms associated with PMS.[9] Mild diuretics (especially spironolactone at doses up to 100 mg each morning) may benefit cyclic edema.

GnRH agonist therapy plus exogenous estrogen and progestin (e.g., 0.625 mg oral conjugated equine estrogen, 5 mg norethindrone acetate) have been tried with variable success. Neither natural progesterone, given in the form of vaginal suppositories,[10] nor large quantities of multiple vitamins or oil of evening primrose are of documented benefit.

Surgical Therapy

Because premenstrual syndrome requires the occurrence of cyclic ovulation, oophorectomy is occasionally considered for patients who have particularly intractable symptoms. However, oophorectomy may create new problems related to estrogen deficiency.

PROGNOSIS

Premenstrual syndrome can cause debilitating symptoms, but intervention can frequently result in substantial improvement. In the absence of oophorectomy or menopause, however, discontinuing treatment can result in recurrence of symptoms.

ABNORMAL UTERINE BLEEDING

EPIDEMIOLOGY AND PATHOBIOLOGY

Abnormal uterine bleeding may occur in 10 to 30% of women of reproductive age but is a warning sign for endometrial cancer if it develops in postmenopausal women. Prompt and accurate diagnosis is essential.

About 20% of abnormal uterine bleeding[11] is postmenarchal bleeding in adolescents, in whom immaturity of the hypothalamic-pituitary-ovarian axis results in anovulation. Another 50% of abnormal uterine bleeding is perimenopausal bleeding related to incipient ovarian failure and menopause (Chapter 222).

Abnormal uterine bleeding with no demonstrable organic genital or extragenital cause (75% of cases) is most frequently associated with anovulation and is appropriately termed *anovulatory* (sometimes termed *dysfunctional*) *bleeding*. Most anovulatory bleeding is due to either estrogen withdrawal or estrogen breakthrough bleeding. In anovulatory women, estrogen stimulates the endometrium unopposed by progesterone. The endometrium proliferates, becomes thicker, and may shed irregularly. Compared with cyclic menses, anovulatory bleeding tends to occur at less frequent intervals, whereas organic lesions tend to cause more frequent bleeding.

During the reproductive years, the causes of uterine bleeding include complications from the use of oral contraceptives; complications of pregnancy, especially threatened, incomplete, or missed miscarriages and ectopic pregnancy; coagulation disorders, most commonly idiopathic thrombocytopenic purpura (Chapter 158) and von Willebrand disease (Chapter 159); and pelvic disease, such as intrauterine polyps, leiomyomas (fibroids), and tumors of the vagina and cervix (Chapter 184). Clear cell adenocarcinoma of the vagina or cervix may occur in women exposed to diethylstilbestrol during fetal life. Affected women may also have congenital abnormalities of the upper vagina, cervix, and uterus. Women with a history of diethylstilbestrol exposure should be reassured that the incidence of malignant change is extremely low. Trauma (coital or otherwise), foreign bodies, systemic illnesses including various endocrinopathies (such as diabetes mellitus, hypothyroidism and hyperthyroidism, Cushing syndrome, and Addison disease), leukemia, and renal disease may also be associated with abnormal bleeding as the presenting manifestation.

CLINICAL MANIFESTATIONS

Heavy menstrual bleeding is now recognized as excessive menses that interfere with physical, social, emotional, and/or material quality of life. Abnormal bleeding may also occur independently of the menstrual cycle.

DIAGNOSIS

All cases of abnormal bleeding should be evaluated, beginning with a thorough history emphasizing the amount and duration of blood loss. Prospective charting of the days on which bleeding occurs may be required to evaluate the bleeding pattern. Complications of pregnancy or a bleeding diathesis must always be excluded.

The findings on physical examination (including the Papanicolaou smear) are normal in anovulatory bleeding except for signs of anemia in the more severe cases. Laboratory tests should include a complete blood count, platelet count, coagulation studies (including screening for von Willebrand disease [Chapter 159]), thyroid function tests (Chapter 207), and fasting blood glucose concentration. Anovulatory bleeding must be a diagnosis of exclusion, with management depending on the age of the patient and the extent of the bleeding.

For all women older than age 35 years and for all patients who are at increased risk for endometrial carcinoma (Chapter 184) because of prolonged anovulatory bleeding, a sample of the endometrium should be obtained by biopsy or by dilation and curettage.

TREATMENT

Even profuse bleeding in hemodynamically stable anovulatory women can almost always be successfully treated by the off-label administration of one combination oral contraceptive pill (Table 220-3) every 6 hours for 5 to 7 days. Bleeding should cease within 24 hours, but patients should be warned to expect heavy bleeding 2 to 4 days after therapy is stopped. If anemia is profound, blood transfusion may be necessary. If the bleeding continues despite therapy, curettage can be performed. Recurrence can be prevented by giving the patient combination oral contraceptive agents cyclically if pregnancy is not desired. If pregnancy is desired, ovulation can be induced.

Acute episodes of anovulatory bleeding can also be treated with conjugated estrogens administered intravenously (25 mg every 4 hours for up to three doses) until bleeding ceases. Progestin therapy (medroxyprogesterone acetate 5 to 10 mg orally for 10 days) should be started simultaneously. Withdrawal

bleeding occurs after cessation of therapy, and the patient can then be treated with oral contraceptive agents (Table 220-3) for at least three cycles.

For individuals with anovulatory bleeding without an episode of profuse bleeding, treatment with cyclic oral contraceptive agents (Table 220-3) or progestin (a standard oral contraceptive pill per day [see Table 220-3] or norethindrone 5 mg daily) can be provided unless pregnancy is desired, in which case ovulation must be induced.

Endometrial ablation by any of several methods is being used increasingly to treat persistent bleeding. However, ablation is not 100% effective, and medical management remains the first line of therapy for most women. Women suffering with uterine fibroids can be treated with oral medication (e.g., elagolix 300 mg twice daily or relugolix 40 mg daily), uterine artery embolization, or surgery (Chapter 184).

Hysterectomy may be an appropriate choice for a small number of women with refractory symptoms. It is also indicated if endometrial sampling suggests malignancy.

PROGNOSIS

The prognosis of abnormal uterine bleeding depends on its cause and treatment. Most cases resolve with effective intervention.

AMENORRHEA

Amenorrhea is the absence of menstruation for 3 months or more in women with past menses (secondary amenorrhea) or the absence of menarche by the age of 15 years regardless of the absence or presence of secondary sex characteristics (primary amenorrhea). Amenorrhea in the absence of pregnancy, lactation, or menopause occurs in about 3 to 4% of women of reproductive age, and it usually is secondary rather than primary.

If an intact genital outflow tract exists and there is no primary disease of the uterus, amenorrhea is a sign of failure of the hypothalamic-pituitary-ovarian axis to produce cyclically the hormones necessary for menses. Amenorrhea is physiologic in the prepubertal girl, during pregnancy, early in lactation, for up to 3 months after the discontinuation of oral contraceptive agents, and after menopause. At any other time, it is pathologic and demands evaluation. Similarly, individuals with menses occurring at infrequent intervals of more than 40 days or having fewer than nine menses per year, termed *oligomenorrhea*, should be evaluated identically to women with amenorrhea.

DIAGNOSIS

Clinical Evaluation

In patients with amenorrhea, even subtle hormonal abnormalities may lead to signs and symptoms. Breast development indicates exposure to estrogens, and the presence of pubic and axillary hair indicates androgenic stimulation.

Patients should be questioned especially closely for evidence of psychological disturbances, dietary and exercise habits,[12] lifestyle, environmental stresses, family history of genetic anomalies, abnormal growth and development, signs of hyperandrogenism (including hirsutism, temporal balding, deepening of the voice, increased muscle mass, clitoromegaly, and increased libido), and signs of defeminization (including decreasing breast size and vaginal atrophy). Any history of galactorrhea should be determined. A history of symptoms related to thyroid and adrenal dysfunction should also be sought (Chapters 207, 208, and 209).

The physical examination should focus on the evaluation of body dimensions and habitus, extent and distribution of body hair, breast development and secretions, and genitalia. In normal adult women, the arm span is similar to the height; in hypogonadal women, the span is generally more than 5 cm greater than the height. The distribution and quantity of body hair should be considered in view of the family history. The extent of any hirsutism should be recorded, preferably by photographs. Other signs of virilization should be sought carefully. Breast development should be graded according to the method of Tanner (Table 218-3). Breast secretion should be sought by applying pressure to the breasts while the patient is seated. Any secretion should be examined microscopically for the presence of perfectly round but variable size fat globules, which indicate galactorrhea. Finally, the female genitalia should be examined carefully because they are such sensitive indicators of the hormonal milieu. The Tanner stage of pubic hair development should be noted (see Table 218-3).

Because sensitivity of the genitalia to androgens decreases fairly early in fetal development, the extent of any virilization is important. Fusion of the labia and enlargement of the clitoris, with or without formation of a penile urethra, are observed in women exposed to androgens during the first 3 months of fetal development (Chapter 214). Significant clitoromegaly in the absence of other signs of sexual ambiguity and in the presence of other signs of virilization requires marked androgenic stimulation and strongly implicates an androgen-secreting neoplasm. The development of the labia minora in postpubertal women indicates the influence of estrogens. Overt anomalies of the distal genital tract and any evidence of obstruction to the escape of menstrual blood should be sought. Under the influence of estrogen, the vaginal mucosa changes during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a dull, gray-pink rugated surface with copious, thick secretions.

The history and physical examination quickly differentiate among several causes of amenorrhea (Table 218-4). The various disorders of sexual differentiation and other anatomic causes are often apparent on inspection. Distal genital tract obstruction should be identified at the time of pelvic examination even if the specific abnormality is not obvious. The physical stigmata of Turner syndrome (Chapter 214) generally make the diagnosis simple. Any sexual ambiguity indicates the need for chromosomal analysis and the measurement of 17α-hydroxyprogesterone to exclude congenital adrenal hyperplasia. Pregnancy and gestational trophoblastic disease may be diagnosed by measurement of human chorionic gonadotropin (hCG). The possibility of intrauterine synechiae or adhesions (Asherman syndrome) must be considered in individuals in whom amenorrhea develops after curettage or endometritis. Tuberculous endometritis, especially in younger women, may also lead to this disorder.

Provocative Testing

Administration of a progestin (typically medroxyprogesterone acetate 5 to 10 mg given orally for 5 to 10 days, or progesterone in oil 100 mg given intramuscularly) can precipitate withdrawal bleeding, which may indicate that sufficient endogenous estrogen was present to allow for endometrial proliferation. This test is of limited value, however, because almost 50% of young women with premature ovarian failure experience withdrawal bleeding in response to progestin.

To ascertain whether the outflow tract is intact, an orally active estrogen, such as 2.5 mg of conjugated estrogen daily for 21 days, with 5 to 10 mg of oral medroxyprogesterone acetate for the last 5 to 10 days, should be administered. Withdrawal bleeding should occur if the endometrium is normal. However,

TABLE 218-3 CRITERIA FOR DISTINGUISHING TANNER STAGES 1–5 DURING FEMALE PUBERTAL MATURATION

TANNER STAGE	BREAST	PUBIC HAIR
1 (Prepubertal)	No palpable glandular tissue or pigmentation of areola; elevation of areola only	No pubic hair; short, fine vellus hair only
2	Glandular tissue palpable with elevation of breast and areola together as a small mound; areolar diameter increased	Sparse, long, pigmented terminal hair chiefly along the labia majora
3	Further enlargement without separation of breast and areola; although more darkly pigmented, areola still pale and immature; nipple generally at or above midplane of breast tissue when individual is seated upright	Dark, coarse, curly hair, extending sparsely over mons
4	Secondary mound of areola and papilla above breast	Adult-type hair, abundant but limited to mons and labia
5 (Adult)	Recession of areola to contour of breast; development of the Montgomery glands and ducts on areola; further pigmentation of areola; nipple generally below midplane of breast tissue when individual is seated upright; maturation independent of breast size	Adult-type hair in quantity and distribution; spread to inner aspects of the thighs in most racial groups

TABLE 218-4 CAUSES OF AMENORRHEA

ANATOMIC CAUSES
Pregnancy
Various disorders of sexual differentiation
Distal genital tract obstruction (müllerian agenesis or dysgenesis)
Gonadal dysgenesis*
Ambiguity of external genitalia (male and female pseudohermaphroditism)
Intrauterine adhesions (Asherman syndrome)
Gestational trophoblastic disease
CHRONIC ANOVULATION
Due to CNS-hypothalamic-pituitary dysfunction
With inappropriate steroid feedback (e.g., polycystic ovary syndrome)
Due to thyroid or adrenal disorders
OVARIAN "FAILURE"
Menopause
Genetic abnormalities
Physical and environmental causes (e.g., chemotherapeutic agents, irradiation)
Autoimmune disorders
Idiopathic

*Gonadal dysgenesis may be viewed as both a disorder of sexual differentiation and a form of gonadal "failure."
CNS = central nervous system.

hysterosalpingography and hysteroscopy may be required for the diagnosis of Asherman syndrome because some patients with a normal endometrium may not have a withdrawal bleed due to obstruction of the cervical os by scar tissue.

Laboratory Findings

Basal levels of FSH, prolactin, and thyroid-stimulating hormone (TSH) should be measured in all amenorrheic and oligomenorrheic women to confirm the clinical impression (Fig. 218-3).[13]

Increased TSH levels with or without increased levels of prolactin imply primary hypothyroidism, and further evaluation for this disorder is indicated (Chapter 207). Although hypothyroidism commonly results in anovulation, amenorrhea occurs in only some hypothyroid women. Menorrhagia and oligomenorrhea may occur as well. The sensitive immunoassays for TSH permit identification of women with hyperthyroidism as well because TSH levels are suppressed in those individuals.

If the prolactin concentration is minimally increased and the TSH level is normal, measurement of the prolactin concentration should be repeated before more extensive evaluation is undertaken because prolactin levels are increased by nonspecific stressful stimuli, sleep, and food ingestion. Prolactin levels may be elevated in as many as one third of women with amenorrhea.

Increased FSH levels (generally above 30 mIU/mL) imply ovarian failure and require further evaluation. Incipient ovarian failure should be considered in any woman with basal FSH levels of 15 mIU/mL or higher other than during the midcycle LH surge. Chromosomal evaluation is indicated if hypergonadotropic amenorrhea begins before age 30 years, and it is often performed in all individuals with elevated FSH levels before age 40 years.

If FSH levels are low or normal, measurement of the free testosterone level may be helpful regardless of any evidence of hirsutism or virilization. Hyperandrogenic women need not be hirsute because some have relative insensitivity of the hair follicles to androgens. Mildly increased levels of free testosterone (and perhaps dehydroepiandrosterone sulfate as well) suggest polycystic ovary syndrome.

Circulating levels of LH and FSH may aid in differentiation of polycystic ovary syndrome from hypothalamic-pituitary dysfunction. LH levels are often elevated in polycystic ovary syndrome so that the ratio of LH to FSH is increased; however, LH levels may be identical to those observed in normal women in the follicular phase. In contrast, levels of LH and FSH are normal or slightly reduced in hypothalamic-pituitary dysfunction. There is some overlap between women with "polycystic ovarian-like" disorders and those with hypothalamic-pituitary dysfunction. Radiographic assessment of the sella turcica is indicated in all amenorrheic women in whom both LH and FSH levels are consistently low (both below 10 mIU/mL) to exclude a pituitary or parapituitary neoplasm (Chapter 205). Other pituitary functions should be evaluated in any individual with significantly impaired LH and FSH secretion. Both total testosterone and dehydroepiandrosterone sulfate levels should be measured in hirsute or virilized women. Testosterone levels greater than 200 ng/dL should lead to investigation for an androgen-producing neoplasm, most likely of ovarian origin. Dehydroepiandrosterone sulfate levels greater

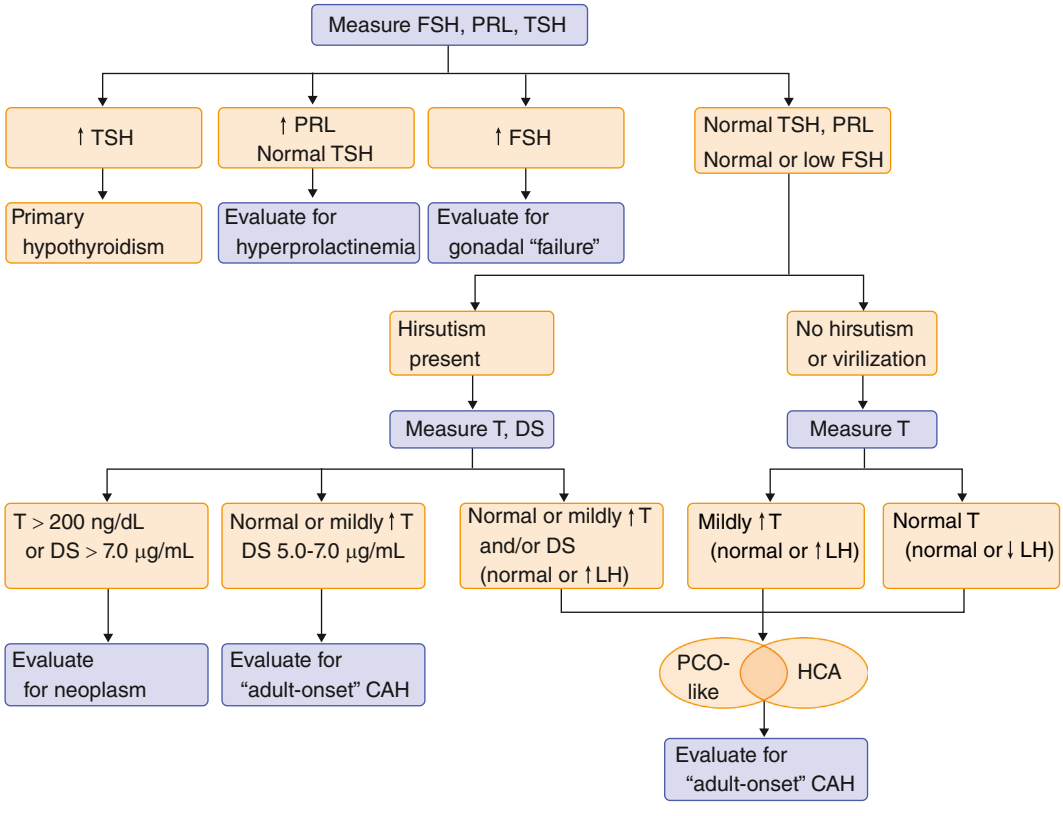

FIGURE 218-3. Biochemical evaluation of amenorrhea. This schema must be considered an adjunct to the clinical evaluation of the patient. See text for details. CAH = congenital adrenal hyperplasia; DS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; HCA = hypothalamic chronic anovulation; LH = luteinizing hormone; PCO-like = polycystic ovarian syndrome–like; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

than 7.0 μg/mL should lead to evaluation for an adrenal neoplasm, and levels between 5.0 and 7.0 μg/mL should lead to evaluation for adult-onset congenital adrenal hyperplasia (Chapter 214).

HYPERGONADOTROPIC AMENORRHEA (HYPOGONADISM, PRIMARY OVARIAN INSUFFICIENCY)

Gonadal failure may begin at any time during embryonic or postnatal development and may result from many causes. Normally, the ovaries fail at menopause, when virtually no functioning follicles remain. However, premature loss of oocytes before the age of 40 years may occur and lead to premature ovarian failure. Circulating gonadotropin levels increase whenever ovarian failure occurs because of decreased negative estrogen feedback to the hypothalamic-pituitary unit.

PATHOBIOLOGY

Causes of premature ovarian failure include genetic causes (e.g., karyotypic abnormalities, single gene mutations, and complex multifactorial polygenic inheritance), physical and environmental causes, and autoimmune disturbances.[14] In addition, menopause may begin earlier than the expected age in some families without any evident pathologic cause.

Genetic Abnormalities

Several pathologic conditions with dysgenetic gonads involve elevated gonadotropin levels and amenorrhea as well as abnormalities of the X chromosome. Gonadal dysgenesis refers to individuals who have undifferentiated streak gonads in the absence of either extragonadal stigmata or abnormalities of sex chromosomes; because individuals with gonadal dysgenesis have the normal complement of oocytes at 20 weeks of fetal age but virtually none by birth, this disorder is a form of premature ovarian failure.

In Turner syndrome (see Chapter 214), phenotypic females have streak gonads composed of fibrous stroma. Most commonly, the second sex chromosome is absent (45,X), but chromosome breakage and mosaicism occur as well.

In pure gonadal dysgenesis, phenotypically female individuals with streak gonads are of normal stature without the physical stigmata of Turner syndrome. Such individuals have either a 46,XX or 46,XY karyotype.

Several regions of the X chromosome can contain mutations that may result in premature ovarian failure. More than 5% of women with 46,XX spontaneous premature ovarian failure have mutations of the *FMR1* gene. For *FMR1*, a CGG repeat sequence occurs, with up to 60 repeats being normal. Expansion to more than 200 repeats leads to fragile X syndrome, with the high level of repeats causing hypermethylation of the gene promoter and silencing of the gene. Female carriers of the premutation have an unstable intermediate number of repeats (i.e., 60 to 199) and the predisposition for premature ovarian failure. This risk is increased if there is a family history of premature ovarian failure and fragile X intellectual disability. Women with mutations in the *FMR1* gene are at risk of having a child with intellectual disability, should they be one of the 6 to 8% of women with premature ovarian failure who conceive spontaneously. A family history of fragile X syndrome, unexplained intellectual disability, dementia, developmental delay of a child, or tremor-ataxia syndrome is reason for genetic counseling.

Trisomy X (46,XXX karyotype) is also associated with premature menopause, although many such individuals have normal reproductive lives. Premature menopause can also occur in mosaic individuals with cell lines with excess X chromosomes. When gonadal abnormalities occur in women with excess X chromosomes, they seem to occur after ovarian differentiation so that some ovarian function is possible. Only later in life do such women develop secondary amenorrhea and premature ovarian failure.

In girls with the rare syndrome of 17α-hydroxylase deficiency involving *p450c17* who survive until the expected age of puberty, sexual infantilism and primary amenorrhea occur together with elevated levels of gonadotropins (also see Chapter 214). Defects in the 20,22-lyase (*p450scc*) or aromatase (*p450arom*) enzymes may also lead to ovarian failure. Women with galactosemia also experience ovarian failure early in life, even when a galactose-restricted diet is introduced early in infancy.

Mutations of several autosomal genes result in premature ovarian failure. Included in this growing list are mutations involving *FSHR* (the FSH receptor gene), *FOXL2* (a forkhead transcription factor associated with the blepharophimosis-ptosis-epicanthus inversus syndrome), *INHA* (the inhibin-α gene), *E1F2B* (a family of genes associated with central nervous system leukodystrophy and ovarian failure), *PMM2* (the gene for phosphomannomutase), *GALT* (the gene for galactose-1-phosphate uridyltransferase), and *AIRE* (leading to autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome). Myotonic dystrophy (Chapter 389), which like fragile X syndrome is caused by an autosomal triple repeat mutation, is similarly associated with premature loss of germ cells from the ovary.

Savage syndrome occurs in young amenorrheic women who have elevated peripheral gonadotropin concentrations, normal (although immature) follicles present on ovarian biopsy, 46,XX karyotype with no evidence of mosaicism, fully developed secondary sex characteristics, and ovarian resistance to stimulation with human menopausal or pituitary gonadotropins. At least some of these women have mutations in the FSH receptor.

Other Causes

Physical and Environmental

Irradiation and chemotherapeutic agents used to treat various malignant diseases may also cause premature ovarian failure. Ovulation and cyclic menses return in some of these patients even after prolonged intervals of hypergonadotropic amenorrhea associated with signs and symptoms of profound hypoestrogenism. In general, the younger the individual at the time of treatment, the less likely she is to have permanent ovarian failure after the completion of therapy. Rarely, mumps (Chapter 340) affects the ovaries and causes ovarian failure.

Autoimmune Disorders

Premature ovarian failure may occur in conjunction with a variety of autoimmune disorders. The most well-known syndrome (autoimmune polyglandular syndrome type 1) involves hypoadrenalism, hypoparathyroidism, and mucocutaneous candidiasis together with ovarian failure (Chapter 212). Testing for adrenal antibodies by indirect immunofluorescence will identify the 4% of women with spontaneous premature ovarian failure who have steroidogenic cell autoimmunity and are at risk for adrenal insufficiency. Thyroiditis is the most commonly associated abnormality. Antibodies to the FSH receptor have been identified in a few cases.

CLINICAL MANIFESTATION AND DIAGNOSES

In patients who have amenorrhea before age 40 years and who manifest symptoms similar to menopause (e.g., infertility, hot flashes, dyspareunia, vaginal dryness), the diagnosis can be confirmed by an elevated FSH level (e.g., >25 mIU/mL) on two occasions, measured at least 4 months apart. Psychological support is important, because depression is common after the diagnosis of premature ovarian insufficiency.

TREATMENT

Women with hypergonadotropic amenorrhea and ovarian failure should be treated identically, regardless of whether they have signs of hypoestrogenism or desire pregnancy. Counseling and psychological support are indicated for women in whom the diagnosis of premature ovarian failure is made. Estrogen replacement is warranted to prevent the accelerated bone loss known to occur in affected women. The estrogen should be given sequentially with a progestin to prevent endometrial hyperplasia (e.g., using 2 mg estradiol daily with 1 mg norethindrone acetate for the final 10 days). Young women with ovarian failure may require twice as much estrogen as postmenopausal women for relief of signs and symptoms of hypoestrogenism. Standard oral contraceptives (see Table 220-3) may be considered for hormone replacement, although other hormone replacement regimens may be cardioprotective (Chapter 222). Surprisingly, women with premature ovarian failure may conceive while taking exogenous estrogen, even in the form of oral contraceptive agents, at the same rate as women not taking estrogen, so barrier contraception should be discussed if pregnancy is not desired.

Women with hypergonadotropic amenorrhea may have a pregnancy and delivery rate of about 6 to 8%. Infertility treatment of young women with hypergonadotropic amenorrhea involves specialist-guided hormone replacement to mimic the normal menstrual cycle and embryo transfer by use of donor oocytes. Whether women with gonadal dysgenesis should be offered pregnancy by use of donor oocytes is now the subject of debate because of a markedly increased incidence of aortic rupture secondary to medial necrosis during pregnancy. Women with Turner syndrome contemplating pregnancy should be counseled regarding the risks.

CHRONIC ANOVULATION

Anovulation can result in either amenorrhea or irregular (generally less frequent) menses. Chronic anovulation, which is the most frequent form of amenorrhea encountered in women of reproductive age, implies that functional

TABLE 218-5 CAUSES OF CHRONIC ANOVULATION

- Chronic anovulation of hypothalamic-pituitary origin
  - Hypothalamic chronic anovulation
    - Psychogenic
      - Exercise associated
      - Associated with diet, weight loss, or malnutrition
      - Anorexia nervosa and bulimia
      - Pseudocyesis
  - Forms of isolated (idiopathic) hypogonadotropic hypogonadism (including Kallmann syndrome)
  - Due to hypothalamic-pituitary damage
    - Pituitary and parapituitary tumors
    - Empty sella syndrome
    - Following surgery
    - Following irradiation
    - Following trauma
    - Following infection
    - Following infarction
  - Idiopathic hypopituitarism
  - Hypothalamic-pituitary dysfunction or failure with hyperprolactinemia (multiple causes)
  - Due to systemic diseases
- Chronic anovulation due to inappropriate feedback (i.e., polycystic ovary syndrome)
  - Excessive extraglandular estrogen production (i.e., obesity)
  - Abnormal buffering involving sex hormone–binding globulin (including liver disease)
  - Functional androgen excess (adrenal or ovarian)
  - Neoplasms producing androgens or estrogens
  - Neoplasms producing chorionic gonadotropin
- Chronic anovulation due to other endocrine and metabolic disorders
  - Adrenal hyperfunction
    - Cushing syndrome
    - Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - Thyroid dysfunction
    - Hyperthyroidism
    - Hypothyroidism
  - Prolactin or growth hormone excess
    - Hypothalamic dysfunction
    - Pituitary dysfunction (microadenomas and macroadenomas)
    - Drug induced
  - Malnutrition

ovarian follicles remain and that cyclic ovulation can be induced with appropriate therapy (Table 218-5).

HYPOTHALAMIC CHRONIC ANOVULATION

DEFINITION

Hypothalamic chronic anovulation represents a heterogeneous group of disorders with similar manifestations. Emotional and physical stress, excessive exercise, nutritional deficiencies, weight loss, reduced body fat, and other unrecognized factors may contribute in varying proportions to the anovulation. Women with hypothalamic chronic anovulation have normal neuroanatomic findings.

Anorexia Nervosa

Individuals with amenorrhea and significant weight loss should be examined for the possibility of anorexia nervosa (Chapter 200).

Isolated Hypogonadotropic Hypogonadism

Affected individuals have an absence of spontaneous pubertal development. Most have functional GnRH deficiency, but some have abnormalities of gonadotropin deficiency localized to the pituitary gland.

Kallmann syndrome is a familial disorder consisting of gonadotropin deficiency, anosmia or hyposmia, and color blindness in men or, more rarely, in women (Chapter 204). Partial or complete agenesis of the olfactory bulb is present on autopsy, accounting for use of the term *olfactogenital dysplasia*. Isolated gonadotropin deficiency in the absence of anosmia occurs as well. Sexual infantilism with a eunuchoid habitus is the clinical hallmark of this disorder, but moderate breast development may occur. Circulating LH and FSH levels are low but almost always detectable. The induction of ovulation requires exogenous gonadotropins and hCG or pulsatile GnRH by a specialist. Estrogen replacement therapy, assuming that pubertal development is complete, with a standard oral contraceptive pill (see Table 220-3), is indicated in these women until pregnancy is desired. If puberty is not initiated or completed, the regimen is complex and is best managed by a reproductive endocrinologist.

Hypopituitarism

Hypopituitarism may be obvious on cursory inspection or sufficiently subtle to require endocrine testing (Chapter 205). Failure to develop secondary sex characteristics (Chapter 217) must always raise the question of hypopituitarism. Ovulation can be induced successfully by a specialist with exogenous gonadotropins when pregnancy is desired and after the hypopituitarism is treated appropriately. Replacement therapy with standard oral contraceptives (see Table 220-3) is indicated if pregnancy is not desired and the pubertal transition has been completed.

HYPERPROLACTINEMIA

Galactorrhea associated with hyperprolactinemia, whatever the cause, almost always occurs together with amenorrhea caused by hypothalamic-pituitary dysfunction or failure. Many conditions can cause excess secretion of prolactin (Chapter 205), but a prolactinoma must be excluded. Hirsutism may be observed occasionally in association with amenorrhea-galactorrhea and hyperprolactinemia. Elevated levels of the adrenal androgens dehydroepiandrosterone and dehydroepiandrosterone sulfate may be observed and may account for the polycystic-type ovaries present in some hyperprolactinemic women.

Failure of the Hypothalamic-Pituitary Unit

The hypothalamic-pituitary unit may fail to function normally in a number of stressful, debilitating, systemic illnesses that interfere with somatic growth and development. Chronic renal failure, liver disease, and diabetes mellitus are the most prominent examples, whereas anorexia nervosa (Chapter 200) represents a potentially reversible cause.

DIAGNOSIS

Abrupt cessation of menses in women younger than age 30 years who have no anatomic abnormalities of the hypothalamic-pituitary-ovarian axis and no other endocrine disturbances suggests a diagnosis of hypothalamic chronic anovulation. Affected individuals tend to be bright, educated, and engaged in intellectual occupations and may well give a history of psychosexual problems and socioenvironmental trauma. Hypothalamic chronic anovulation is characterized by low to normal levels of gonadotropins and relative hypoestrogenism. However, affected women rarely present with signs and symptoms of estrogen deficiency. In women who appear to have hypothalamic chronic anovulation, a CT or MRI should be obtained to exclude a pituitary lesion as the cause of the hypogonadotropic hypogonadism.

TREATMENT

Psychological counseling, cognitive-behavioral therapy, or a change in lifestyle, especially for women engaged in strenuous exercise programs, may be effective in inducing cyclic ovulation and menses in women with functional hypothalamic chronic anovulation. For women who desire pregnancy, ovulation can also be induced with clomiphene citrate (50 to 100 mg/day for 5 days beginning on the third to fifth day of withdrawal bleeding). Treatment by a fertility expert with exogenous gonadotropins to induce follicular maturation followed by hCG to induce follicular rupture may be effective in women who do not ovulate in response to clomiphene. Some women with hypothalamic chronic anovulation have low circulating levels of leptin and may ovulate after therapy with recombinant leptin.

If chronic anovulation persists, osteoporosis should be prevented with daily oral conjugated or esterified estrogens (0.625 to 1.25 mg), ethinyl estradiol (20 μg), or micronized estradiol-17β (1 to 2 mg) or transdermal estradiol-17β (0.05 to 0.10 mg) daily, with oral medroxyprogesterone acetate (5 to 10 mg) added for the first 12 to 14 days of each month. Sexually active women can be given oral contraceptive agents (Table 220-3) as an alternative. Adequate ingestion of calcium should be ensured regardless of therapy. Contraception is needed for sexually active women with hypothalamic chronic anovulation because the functional defect is mild and may resolve spontaneously at any time, with ovulation occurring before any episode of menstruation.

CHRONIC ANOVULATION RELATED TO INAPPROPRIATE FEEDBACK

Polycystic Ovary Syndrome

DEFINITION

Polycystic ovary syndrome (PCOS) is a heterogeneous disorder with considerable clinical and biochemical variability among affected individuals.[14] Polycystic ovary syndrome is defined by any two of the following: (1) oligo-ovulation or anovulation, (2) hyperandrogenism, or (3) polycystic ovaries on ultrasound in women in whom other etiologies have been eliminated.

EPIDEMIOLOGY AND PATHOBIOLOGY

Polycystic ovary syndrome affects about 6 to 12% of women of reproductive age, without any obvious geographic or ethnic differences, and it is the most common endocrine abnormality of women in this age group. More than 50% of affected women develop type 2 diabetes by age 40 years. Obesity contributes to the polycystic ovarian syndrome, and the increase in the prevalence of obesity is contributing to an increased prevalence of this syndrome.

In polycystic ovary syndrome, the amenorrhea or oligomenorrhea results from inappropriate feedback of gonadal steroids from the ovaries. The hypothalamic-pituitary unit is intact, but the functional derangement, perhaps involving insulin-like growth factors within the ovary, results in abnormal secretion of gonadotropins. Polycystic ovary syndrome is characterized by insulin resistance and compensatory hyperinsulinemia in affected women across racial and ethnic groups, thereby implying that a common defect may be present. Increasing evidence points to specific genetic abnormalities, such as alterations in *CYP17* and *CYP19*.

CLINICAL MANIFESTATIONS

Although patients usually present with amenorrhea, hirsutism, and obesity, affected women may instead complain of irregular and profuse uterine bleeding, may not have hirsutism, and may be of normal weight. In the primary syndrome, the irregular menses, mild obesity, and hirsutism begin during puberty and typically become more severe with time, but they may improve in the years just before menopause.

DIAGNOSIS

Excess androgen from any source or increased extraglandular conversion of androgens to estrogens can lead to the typical findings of polycystic ovary syndrome.[15] Included are such diverse disorders as Cushing syndrome (Chapter 208), mild congenital adrenal hyperplasia (Chapter 214), virilizing tumors of adrenal or ovarian origin (Chapters 184 and 208), hyperthyroidism and hypothyroidism (Chapter 207), and obesity (Chapter 201). After exclusion of these causes, two of the following three are required for a diagnosis of polycystic ovary syndrome: (1) hyperandrogenism (clinical or biochemical), (2) oligo-ovulation or anovulation, and (3) polycystic ovaries on ultrasound examination or at surgery. Based on this definition, the diagnosis of polycystic ovary syndrome can be made in women who ovulate normally,

Patients are well estrogenized regardless of whether they present with primary or secondary amenorrhea or dysfunctional bleeding. LH concentrations tend to be elevated, with relatively low and constant FSH levels, but both may be in the normal range for the follicular phase of the menstrual cycle. Levels of most circulating androgens, especially testosterone, tend to be mildly elevated. Hirsutism should be evaluated as detailed in Chapter 409.

A particularly severely affected subset of women present with marked obesity, anovulation, mild glucose intolerance with high levels of circulating insulin, acanthosis nigricans, hyperuricemia, severe hirsutism, and elevated circulating androgen levels. These women have hyperthecosis of the ovaries, in which the androgen-producing cells in the stromal, hilar, and thecal regions are increased greatly in number.

TREATMENT

Patients generally require therapy for hirsutism (Chapter 409), for induction of ovulation if pregnancy is desired, and for prevention of estrogen-induced endometrial hyperplasia and cancer. No ideal therapy exists,[16,17] so the therapeutic approach must be individualized. The risks for metabolic syndrome, cardiovascular disease (Chapter 40), and diabetes mellitus (Chapter 210) are increased, because of the increased androgens, insulin resistance, and commonly associated hyperlipidemia (Chapter 190).

Medical Therapy

In the anovulatory woman not desiring pregnancy who is not hirsute, therapy with intermittent progestin administration (such as medroxyprogesterone acetate, 5 to 10 mg orally for 10 to 14 days each month) or oral contraceptives (Table 220-3) can reduce the increased risk for endometrial carcinoma that is present in such a woman with unopposed estrogen. All women using intermittent progestin administration should be cautioned about the need for effective contraception if they are sexually active because these agents do not inhibit ovulation when they are administered intermittently.

Improvements in insulin sensitivity through lifestyle changes (e.g., exercise [Chapter 14] and diet [Chapter 13]) or pharmacologic intervention consistently improve the reproductive and metabolic abnormalities. Metformin (1500 to 2000 mg daily in divided doses) can suppress hepatic gluconeogenesis, improve insulin sensitivity, reduce levels of insulin and androgen, and increase the likelihood of ovulation. Resumption of ovulation may occur in up to 60 to 70% of affected women.

Treatment Considering Pregnancy

Oral contraceptive agents (Table 220-3) are the first line of therapy to protect against endometrial hyperplasia in hirsute anovulatory women who do not desire pregnancy. In women who desire pregnancy, letrozole (e.g., 5 mg on days 3 to 7 after the start of the last menstrual period) is the preferred therapy, and both it and clomiphene citrate (50 mg on days 3 to 7 after the start of the last menstrual period) are preferred over metformin (500 mg to 2000 mg daily) to induce ovulation,[A6] and about 75 to 80% of women conceive with such therapy. Other methods to induce ovulation under the direction of a specialist include exogenous gonadotropins plus hCG, or laparoscopic ovarian surgery with multiple punctures of the ovary by diathermy or laser.

Laparoscopic ovarian surgery can achieve unifollicular ovulation or make it easier for the medical induction of ovulation, but it increases the risk of ovarian adhesions, which themselves lead to infertility. Surgery is often limited to the small subset of women who do not respond to medical therapy.

OTHER ENDOCRINE CAUSES

Adrenal hyperfunction (Chapter 208) causes chronic anovulation by inducing a polycystic ovarian-like syndrome secondary to increased secretion of adrenal androgens. Both hyperthyroidism and hypothyroidism (Chapter 207) are associated with a variety of menstrual disturbances, including dysfunctional uterine bleeding and amenorrhea as a result of alterations in the metabolism of androgens and estrogens. These metabolic changes in turn result in inappropriate steroid feedback and chronic anovulation.

INFERTILITY

DEFINITION

According to the World Health Organization (WHO), infertility is "a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse." Sterility is total inability to reproduce. More than 10% of couples in the United States seek medical assistance for infertility.

The requirements for pregnancy to occur are several:

- The male must produce adequate numbers of normal, motile spermatozoa.
- The male must be capable of ejaculating the sperm through a patent ductal system.
- The sperm must be able to traverse an unobstructed female reproductive tract.
- The female must ovulate and release an ovum.
- The sperm must be able to fertilize the ovum.
- The fertilized ovum must be capable of developing and implanting in appropriately prepared endometrium.

In approximately 40% of cases, infertility is caused by the male (Table 218-6). In one third of couples, more than one cause contributes to the infertility.

Peak age for fertility in the female is age 25 years. For nulliparous women of this age, unprotected intercourse produces conception after an average of 5.3 months. For parous women, the average duration of intercourse until conception is 2.7 months. The reproductive performance of couples is influenced by the ages of the female and male partners, the frequency of intercourse, and the length of time the couple has been attempting to conceive. Reproductive performance declines in both females and males after age 25 years.

DIAGNOSIS

Couples who complain of infertility merit evaluation regardless of the length of infertility. Clinician-directed evaluation is warranted in all women who wish to become pregnant if conception has not occurred within 12 months of regular unprotected intercourse, and it is warranted in women ages 35 years or older after 6 months.

The evaluation begins with a detailed history and physical examination of both partners. The couple should be questioned together and separately, because separate interviews may uncover information that would not be imparted in the presence of the partner.

Initial evaluation for infertility includes assessment of semen; documentation of ovulation by basal body temperature, serum progesterone determination 6 to 8 days before menses, serum thyroid hormone, or (rarely) endometrial biopsy less than 3 days before onset of menses; and evaluation of the female genital tract by hysterosalpingography or sonohysterography.

Diagnostic laparoscopy with tubal dye instillation may infrequently be performed if results of all previous tests are normal, because 30 to 50% of

Idiopathic or unexplained (<10%)

women have endometriosis or tubal disease diagnosed by surgical evaluation. Alternatively, patients with initial normal findings may be merely treated as having idiopathic infertility.

TREATMENT

Treatment must be predicated on the findings of the infertility evaluation.[18] Low sperm count or poor motility is best treated either by donor insemination or in vitro fertilization with intracytoplasmic injection of a single viable sperm into each oocyte. Obstruction of the fallopian tubes may be amenable to surgical intervention, but success rates are often greater with in vitro fertilization. Endometriosis causing infertility may be treated by surgery or various suppressive drugs as indicated, but in vitro fertilization may be indicated.

Induction of ovulation in anovulatory women should never be attempted until serious disorders precluding pregnancy are excluded or treated. Furthermore, ovulation induction should not be used in women with ovarian failure because they are unresponsive to any form of induction of ovulation.

Clomiphene citrate (50 mg daily for 5 days, begun on the third to fifth days after spontaneous or induced uterine bleeding) is the first-line agent to induce ovulation in women who do not have hyperprolactinemia and who have the ability to release LH and FSH. Clomiphene, which appears to act as an antiestrogen, stimulates gonadotropin secretion by the pituitary gland to initiate follicular development. If ovulation is not achieved in the first cycle of treatment, subsequent cycles increase the daily dose in a stepwise fashion in 50-mg increments to a maximum of 200 to 250 mg daily for 5 days. The highest dose should be continued for 3 to 6 months before the patient is regarded as unresponsive to clomiphene. Off-label oral letrozole by a specialist is equivalent to clomiphene for inducing ovulation with a slightly lower frequency of multiple gestation.[A7] The ovulatory surge of LH may occur 5 to 12 days (average, 7 days) after the completion of the last day of clomiphene treatment, so couples are advised to have intercourse every other day during this interval. Ovulation can be documented by monitoring changes in basal body temperature or preferably by measuring the serum progesterone level 14 days after the last clomiphene dose. Intrauterine insemination, rather than timed intercourse, optimizes success. If pregnancy does not result, menses should occur after 3 weeks. Withdrawal bleeding with progestin can be induced if the patient fails to bleed within 4 weeks of therapy and if a serum hCG level documents that the patient is not pregnant. Testing the urine for an LH surge may also be useful in timing ovulation.

Of appropriately selected patients, 75 to 80% ovulate, and 40 to 50% can be expected to become pregnant. About 15% of pregnancies can be expected with each ovulatory cycle. The multiple pregnancy rate is about 8%, with almost all being twins. The incidence of congenital anomalies is not increased.

Side effects of clomiphene are uncommon and rarely serious. The most serious ones include vasomotor flushes (10%), abdominal discomfort (5%), breast tenderness (2%), nausea and vomiting (2%), visual symptoms (1.5%), and headache (1%). Ovarian enlargement may occur but is rare (5%), and clomiphene does not appear to increase the risk for epithelial ovarian cancer.

The administration of hCG at 7 days after the last day of clomiphene induces ovulation about 36 hours later and may be helpful in selected couples. Low-quality evidence suggests that the addition of dexamethasone 0.5 mg orally at bedtime to blunt the nighttime secretion of adrenocorticotropic hormone may be useful in hyperandrogenic women who fail to ovulate in response to clomiphene.

Women who do not respond to clomiphene typically require exogenous gonadotropins and hCG or perhaps pulsatile GnRH to induce ovulation. Exogenous gonadotropins are typically administered (intramuscularly or subcutaneously, depending on the preparation) at doses of two to four vials, each containing 75 IU, for 5 to 12 days to achieve follicular development as monitored by ultrasonography and serum or urinary estradiol concentrations. Then hCG (5000 to 10,000 IU) is administered as a single intramuscular dose when follicular maturation is apparent. The hCG should be withheld if more than three follicles mature together. GnRH analogs (ganirelix acetate or cetrorelix 0.25 mg daily) are used to suppress endogenous follicular activity before the initiation of exogenous gonadotropin therapy and continued until hCG is given. Ovulation can be induced in almost 100% of patients, but pregnancy occurs in only 50 to 70%. There is no increased risk for congenital anomalies with exogenous gonadotropins and hCG. The rate of multiple pregnancies with exogenous gonadotropins and hCG may approach 30%, with 5% being triplets or more. Because of the expense and the complication rate, thorough evaluation should be performed to exclude other causes of infertility before exogenous gonadotropins and hCG are used.

Ovarian hyperstimulation syndrome, which is the major side effect of exogenous gonadotropin therapy, may be life-threatening. The ovaries enlarge remarkably, with multiple follicle cysts, stromal edema, and multiple corpora lutea. Fluid shifts from the intravascular space into the abdominal cavity, with resultant hypovolemia and hemoconcentration. The most serious complications may include thromboembolism, renal failure, adult respiratory distress syndrome, and hemorrhage from ovarian rupture. Treatment is conservative, with monitoring of fluid and electrolyte status. Pelvic examinations should not be performed for fear of rupturing the ovaries. The hyperstimulation generally resolves slowly over about 7 days but persists longer if the cycle results in pregnancy.

In cases of unexplained infertility, clomiphene citrate or exogenous gonadotropins can be combined with intrauterine insemination of spermatozoa.[19] The intent is to increase conception rates by assuring access of sperm to several oocytes. This procedure is safe and effective,[A8] but multiple (sometimes high-order) gestations are a significant risk. The risk for multiple gestation and the costs are reduced if women who have not conceived with ovarian stimulation and natural insemination proceed immediately to treatment by in vitro fertilization.

Hyperprolactinemic Women

Both bromocriptine (2.5 mg daily) and cabergoline (0.25 mg twice weekly) are effective in inducing ovulation and pregnancy in about 80% of hyperprolactinemic women. The drug should be stopped when pregnancy is confirmed. Most women with prolactin-secreting pituitary tumors remain asymptomatic during pregnancy. It is rare for a patient with either a microadenoma or a macroadenoma to develop a problem related to the tumor that affects either the mother or the fetus during pregnancy. However, formal assessment of visual fields and computed tomography or magnetic resonance imaging should be performed in any patient experiencing suggestive symptoms. Symptoms generally abate with institution of therapy with a dopamine agonist. No adverse effects of dopamine agonists on fetuses or pregnancies have been reported.

Assisted Reproductive Technologies

The assisted reproductive technologies, in which by definition both eggs and sperm are handled outside of the body, are commonly used to treat infertile couples with tubal disease, endometriosis, oligospermia and azoospermia,

sperm antibodies, and unexplained infertility, or women whose eggs were preserved prior to cancer therapy.[20] In vitro fertilization involves ovarian hyperstimulation, retrieval of oocytes, fertilization, embryo culture, and embryo transfer. Ovarian hyperstimulation with clomiphene citrate and exogenous gonadotropins, gonadotropins alone, or a GnRH agonist or antagonist plus gonadotropins typically causes 1 to 20 oocytes to mature, depending on the patient's age and ovarian reserve. After follicular growth is judged sufficient by ultrasound examination, hCG is given to induce final follicular maturation. About 34 hours after the administration of hCG, the oocytes are retrieved by direct needle puncture of each follicle, usually transvaginally under ultrasound guidance. The oocytes are then inseminated in vitro with washed sperm, or a single sperm is injected directly into a single egg (so-called intracytoplasmic sperm injection). The embryos are cultured for about 40 to 120 hours, after which one or more embryos are transferred to the uterine cavity. Embryos may be cultured to the blastocyst stage (at 120 hours) before transfer. Additional embryos can be frozen in liquid nitrogen for transfer in a subsequent natural cycle. The success rate is most dependent on the age of the woman. In the United States the percentage of cycles resulting in live births ranges from 40% in women younger than age 35 years to 12% in women age 41 to 42 years. Approximately 4 to 9% of pregnancies are twins, and 0.1% are triplets or higher-order multiples. The early embryo can be tested preimplantation for genetic abnormalities that are known or identified by preconception screening, thereby allowing only unaffected embryos to be transferred in families with recognized and testable genetic abnormalities. Uterus transplantation is an emerging option for infertile women who have a nonfunctioning or absent uterus.[21]

SEXUAL FUNCTION AND DYSFUNCTION

Sexual Function

DEFINITION

Sexual responses historically have been divided into four phases: excitement, plateau, orgasm, and resolution. With sexual arousal and excitement, vasocongestion and muscle tension increase progressively, primarily in the genital region, manifested by vaginal lubrication in the female. The lubrication is due to formation of a transudate in the vagina. Sexual excitement is initiated by any of a variety of psychogenic or somatogenic sexual stimuli and must be reinforced to result in orgasm. With continued stimulation, the excitement phase increases in intensity into a plateau phase, during which a high state of sexual interest is maintained. The plateau phase may be short or long, and it is from this phase that an individual can shift to orgasm. The orgasmic phase, which tends to be brief, is characterized by rapid release from the developed vasocongestion and muscle tension. The orgasmic release is also known as the climax because peak psychological and physical intensity is achieved, with an attendant feeling of satisfaction. Copious secretions and transudate may flow during orgasm in women. Characteristic genital and extragenital responses occur during these phases. Estrogens magnify the sexual responses, but responses may occur in estrogen-deficient women. For women, these changes occur in the breasts and in the pudendal region and are variable from one response cycle to another. For some women, excitement proceeds quickly through plateau to orgasm, and orgasm is explosive and accompanied by vocalization and involuntary contractions of the pelvic skeletal muscles. For other women, the responses are slow in building, controlled in amplitude, and long lasting. For a few women, orgasm never occurs; for many, it is intermittently absent.

The somatic sensate focus enabling orgasmic release is variable and may include stimulation of the breasts, vagina, or clitoris. The psychological aspect of coitus may involve concentration on the current partner or act or on fantasies about other times and persons. Although orgasms may vary in physiologic intensity, what is important is psychological satisfaction. Satisfaction for both men and women may be had without orgasm. Women seek sexual experiences for intimacy as well as for sexual gratification. Women may be receptive to or seek out sexual stimuli to enhance intimacy. Biologic and psychological factors contribute to the processing of these stimuli and can enhance arousal and desire simultaneously.

Sexual Dysfunction

Women may seek consultation because of disturbances in normal sexual arousal or orgasm[22] or because of pain with intercourse (dyspareunia).[23] Such sexual dysfunction may be due to either organic or functional disturbances.

A variety of diseases affecting neurologic function, including but not limited to diabetes mellitus (Chapter 210) and multiple sclerosis (Chapter 380), may prevent sexual arousal. Debilitating systemic diseases, such as malignant disease, may also affect sexual function indirectly. Local pelvic disorders, such as endometriosis and vaginitis, cause dyspareunia and may lead to sexual avoidance. Estrogen deficiency causing vaginal atrophy and dyspareunia is a relatively common cause of sexual dysfunction.

Vaginismus, which involves involuntary contractions of the muscles surrounding the introitus, also leads to dyspareunia. It is a conditioned response engendered by a previous real or imagined traumatic sexual experience.

Feelings of guilt (caused by incest or rape, as examples), of inadequacy (caused by hysterectomy or mastectomy), or of depression or anxiety may lead to failure to be aroused. Failure to achieve orgasm may be viewed as a dysfunction if the woman is frustrated or dissatisfied.

TREATMENT

Treatment of sexual dysfunction should eliminate functional causes and provide the patient, often together with her partner, with appropriate psychological counseling. Behavioral modification is effective in treating many women with psychological sexual dysfunction.[A9,24] Sexual satisfaction also can be increased by treating women with testosterone, but dosing guidelines are not clear. Such therapy cannot be considered standard care based on current evidence.

INTERRUPTED PREGNANCY

About 10% of known pregnancies in women under age 30 years end in miscarriage, and this percentage increases to over 50% by age 45 years. About half of these miscarriages occur within the first 6 weeks, but the rate is likely much higher given the number of early miscarriages before pregnancy is confirmed. Expert evaluation is required to be sure that no placental or fetal tissue (incomplete miscarriage) remains unexpelled. For delayed or silent miscarriage, nonviable tissue that has not yet been expelled can be expelled by treatment with oral mifepristone (200 mg) combined with vaginal, oral, or sublingual misoprostol (800 mg) 2 days later.[A10] If medical therapy is unsuccessful, dilation and curettage may be performed. Persistent pregnancy of unknown location can be treated actively with methotrexate (50 mg/m^2 intramuscularly).[A11]

Tubal pregnancy, which manifests as pelvic pain and is often accompanied by light vaginal bleeding, is an emergency that requires operative intervention before tubal rupture and life-threatening hemorrhage occur. It must be suspected whenever a woman of childbearing age develops acute pelvic pain or marked lower abdominal pain or cramping, especially if a menstrual history reveals a missed period.[25] The choice between methotrexate or surgical intervention should be considered based upon the clinical scenario.

Voluntary termination of pregnancy is usually accomplished medically (as for silent miscarriage) but can also be performed interventionally (Chapter 220).

219 APPROACH TO WOMEN'S HEALTH

KAREN M. FREUND

An approach to the care of women must go beyond an understanding of differences in the incidence of disease between men and women. Providers need to consider the impact of sex differences (differences based on genetic and hormonal differences) and gender differences (differences attributable to the roles men and women are ascribed in society).[1] Therapeutic decisions should take into account both genetic and environmental differences in the presentation of disease and the effectiveness of therapeutic options, the patient's reproductive life stage, comorbid conditions, and the social and cultural contexts of care. The increased number of women participating in clinical research improved knowledge about women's health, but gaps remain regarding the gender-specific impact of new therapies and interventions owing to a lack of data on the heterogeneity of impact by sex and gender.[2]

LIFESPAN GROUPS

Many important women's health issues are linked to the social, psychological, and biologic context at certain ages and stages of life. When considering both preventive care and common causes of mortality and morbidity, these lifespan stages provide a context for organizing care (Table 219-1).

For most women, young adulthood (15 to 44 years) is marked by social transitions in family structure, such as forming one's own family, parenting, and entering the work force. Competing demands of career development and of child and eldercare needs affect both a woman's health and her own health care. During this age range, mortality rates are low, so health visits can focus on behavioral decisions that will influence the risk for future disease, such as sexual behavior, smoking (Chapter 363), alcohol (Chapter 364) and drug use (Chapter 365), diet (Chapter 13), and exercise (Chapter 14). Major sources of morbidity include intentional and unintentional injury, including interpersonal violence (Chapter 223) and motor vehicle injuries. Human immunodeficiency virus (HIV; Chapter 360) is a leading cause of morbidity and mortality in this age group. Depression and anxiety (Chapter 362) are common in this and all life stages. Reproductive issues (Chapter 218) are considered in most therapeutic decisions.

TABLE 219-1 IMPORTANT HEALTH ISSUES FOR WOMEN THROUGH THE LIFESPAN

	AGES		
ISSUE	***15-44 yr.***	***45-65 yr.***	***65+ yr.***
Behavioral issues	Risk behaviors Sexual behavior Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Exercise
Social roles and needs	Entering work force Relationship transitions Parenting Caregiving to several generations	Caregiving to several generations Transitions in family and work environments	Losses and social isolation Poverty due to lower lifetime earnings
Reproductive issues	Reproductive health issues	Menopause transition	
Injury	Intentional and unintentional interpersonal violence Motor vehicle injuries		Falls
Common causes of mortality and morbidity	Depression Anxiety HIV/AIDS	Cancer Obesity Diabetes Depression Anxiety	Cardiovascular disease Cancer Cognitive decline Osteoporosis Osteoarthritis Incontinence Depression Anxiety

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

The middle years (ages 45 to 65 years) continue to be influenced by behavioral decisions, especially diet, exercise, and alcohol and substance use. The social context includes role changes as children reach adulthood; caregiving responsibilities are now for dependent children and possibly grandchildren, as well as aging parents. The menopausal transition (Chapter 222) may be accompanied by new symptomatic concerns. Common causes of morbidity, including diabetes (Chapter 210) and obesity (Chapter 201), now reflect earlier behavioral decisions. Cancer is the leading cause of mortality.

Health issues in older women (65+ years) may occur in the context of loss of function and independence. Because women commonly survive their male partners, they are more likely at this stage of life to be unpartnered. Compared with older men, older women have a greater number of social needs, including social isolation, depression, and poverty from accumulated lower lifetime earnings. Cardiovascular disease is the major cause of mortality, followed by cancer, cerebrovascular disease, chronic obstructive lung disease, and pneumonia. Loss of independence is related to cognitive decline (Chapter 371), osteoarthritis (Chapter 241), osteoporotic fractures (Chapter 225), and incontinence (Chapter 115).

HEALTH DISPARITIES AMONG WOMEN

The health status of women is heavily influenced by racial and ethnic differences in outcomes for most common causes of mortality and morbidity. Black Americans, women from many Asian and Pacific Island nations, Native Americans, and women of Latino background share poorer outcomes for a wide variety of conditions (Chapter 4). This broad finding of poorer outcomes across many diverse ethnic and racial groups[3] emphasizes the social determinants of health (e.g., income, education, violence, housing, and food insecurity, among others; see Chapter 4). Common recommendations for health promotion, including a diet low in animal fats and processed sugars but high in whole grains, fruits, nuts, and vegetables, along with regular exercise, such as walking, may be difficult to follow in high-crime neighborhoods or in locales where a variety of affordable, nutritious food options are not available. Barriers to health care access and poor adherence to medical therapy are more common in low-income women, who may have difficulty scheduling appointments that do not interfere with their work schedules or unpaid time off from clerical or service jobs. Low health literacy and cultural barriers can add to challenges in accessing health care. The need to care for dependent children or elders may interfere with women's ability to address their own health care needs (Chapter 4).

COMMON CAUSES OF MORTALITY IN WOMEN

CARDIOVASCULAR DISEASE

Cardiovascular disease (Chapter 40) is the overall leading cause of death in women. However, because cardiovascular-related death occurs most often in women older than age 65 years, its impact is often under-recognized or underestimated. Race and ethnicity play a large role in the risk for cardiovascular disease; Black women have much higher incidence and mortality rates than any other racial or ethnic group, and Latinas and Asian women also have higher rates than White populations.

The incidence rate of cardiovascular disease in women lags 10 years behind that of men from ages 40 through 70 years; that is, a 65-year-old woman has a similar risk to a 55-year-old man. There is no abrupt increase in the risk of cardiovascular disease at menopause in women, thereby suggesting that menopausal changes in estrogen or progesterone do not account for this sex difference. Randomized clinical trials have confirmed that combined estrogen/progestin hormone therapy in women does not prevent cardiovascular disease and is not indicated for cardiovascular disease prevention, but conjugated estrogen alone may reduce the risk of heart disease over the following 18 years when begun in women ages 50 to 59 years.[A1] Estrogen monotherapy or combined estrogen/progestin therapy has complex systemic effects, and the net rates of adverse outcomes when used for chronic disease prevention may vary according to an individual woman's risk factor profile. For example, data suggest an overall benefit when estrogen therapy is started between the ages of 50 to 59 years but not if started later.[4] Therefore, an individualized risk stratification approach is advocated in menopausal women who are otherwise potential

ABSTRACT

The approach to the care of women should consider both the impact of sex differences (i.e., differences based on genetic, hormonal, and other biologic differences), as well as gender differences (i.e., differences related to the roles men and women play in society, including occupation and environmental exposures). A lifespan perspective guides an understanding of the common causes of morbidity and mortality by age and can inform preventive strategies. Providers caring for women of reproductive potential should consider the reproductive impact of every medication prescription. The prevalence, presentation, and management of many common conditions differ between women and men, including cardiovascular disease, cancer, obesity, osteoporosis, and behavioral health issues. However, the precise contribution of sex as compared with gender roles remains uncertain. Racial and ethnic disparities in outcomes on a wide variety of health conditions almost always reflect social determinants of health rather than genetic determinants.

candidates for hormone therapy because of other indications (see Chapter 222). Supplementation of calcium and vitamin D, which can improve bone health in women (Chapter 225), is not indicated to prevent cardiovascular disease.[A2] Other risk factors for cardiovascular disease in women are the same as those in men: elevated lipid levels (Chapter 190), lack of physical activity, obesity (Chapter 201), smoking (Chapter 363), hypertension (Chapter 64), and diabetes (Chapter 210). Women with diabetes have the same risk for cardiovascular disease as men of the same age with diabetes.

However, there are notable disparities in the burden of coronary heart disease among some groups of women, especially women who are disadvantaged because of race, ethnicity, income level, and educational attainment. Cigarette smoking continues to be an important behavioral risk factor for cardiovascular disease, especially in younger women, Native American women, and women with low incomes and low educational attainment. The incidence of many known risk factors, including obesity, hypertension, and hypercholesterolemia, is greater in Black women than in White women. Furthermore, data suggest that women are less likely to receive risk factor reduction therapy, a reflection of an inertia caused by clinicians' misperceptions of their risk for heart disease.

The presentation of coronary artery disease in women differs from that in men. Although chest pain is the most common presentation in women, atypical and noncardiac pain is a more frequent presentation in women than in men, and fewer women have typical chest tightness or pressure as their presenting complaint.[5] For this and other reasons, women often face delays in seeking and receiving emergency care for an acute coronary syndrome (Chapter 57) or acute myocardial infarction (Chapter 58), thereby increasing their risk for death and recurrent myocardial infarction.[6]

Medical management is similar for men and women with acute coronary syndromes (Chapter 57) and acute myocardial infarction (Chapter 58). Women with ST-segment-elevation myocardial infarction or any high-risk women with non–ST-segment-elevation myocardial infarction obtain the same benefits from either percutaneous cardiac interventions of coronary bypass graft surgery (Chapter 59) as do men, after controlling for other comorbid conditions, but women commonly have lower rates of revascularization. Recent randomized clinical trials indicate similar benefits of new therapies for heart failure for women and men, including sodium-glucose cotransporter-2 inhibitors,[A3] defibrillator use,[A4] and transitions of care support.[A5]

U.S. guidelines for the management of lipid disorders (Chapter 190) are based on 10-year risk of cardiovascular disease as well as absolute lipid levels.[7] Although these guidelines are not gender specific, they attempt to avoid overtreatment of younger women at very low risk while avoiding undertreatment of women with the lower low-density lipoprotein (LDL) cholesterol level but much higher overall risks of cardiovascular disease. High-intensity statin therapy is recommended as secondary prevention for women who have clinical atherosclerotic disease, as well as for primary prevention for women who have a 20% or greater risk of atherosclerotic cardiovascular disease, an LDL cholesterol level higher than 190 mg/dL, or diabetes and a 7.5% or greater 10-year risk of atherosclerotic cardiovascular disease (Chapter 190). A moderate-intensity statin is recommended for lower risk women with diabetes or with a 5 to 20% 10-year risk of atherosclerotic cardiovascular disease. Women lag behind men in use of medical therapy for lipid disorders, perhaps in part because of higher reported rates of adverse effects, especially from statins; however, most patients who report such symptoms can successfully use statins after a blinded trial (see Chapter 190).

TYPE 2 DIABETES

The rates of type 2 diabetes (Chapter 210) continue to rise, with a greater risk in women who are overweight, obese, or physically inactive. Rates are higher in many racial and ethnic groups including Black, Asian, Native American, and Latina women than among White women. Lifestyle changes (primarily diet and exercise) can reduce the incidence of type 2 diabetes.[A6] No randomized clinical trials have shown that screening for diabetes is beneficial, but current U.S. guidelines recommend screening overweight or obese adults with a high A_{1C} level as part of their cardiovascular risk assessment beginning at age 35 and continuing to age 70 years.[8] For women who develop gestational diabetes (Chapter 221), the risk of developing type 2 diabetes later in life increases five-fold,[9] so screening with hemoglobin A_{1C} levels at 6 to 12 weeks postpartum and every 3 years thereafter is recommended.[10]

The incidence of diabetes is rising in women at younger ages, with significant perinatal and maternal health implications. Ongoing discussion of fertility control and family planning is critical in diabetic women with childbearing potential. Tight glycemic control before conception and through the first trimester is critical to reduce the risk for birth anomalies, and it is important later in pregnancy to reduce the risk for adverse fetal events, including macrosomia (large for gestational age) and preterm birth (Chapter 221). Ideally, women planning a pregnancy should switch from oral agents to insulin, with home glucose monitoring for tight control (Table 219-2). Risks of maternal complications from diabetes including vascular disease, retinopathy, hypertension, preeclampsia, renal disease, and neuropathy are general related to glycemic control before and during pregnancy and usually not specifically due to pregnancy itself.

CANCER

Cancer is the leading cause of death in women ages 40 through 65 years, and it is the leading cause of years of life lost in women younger than age 65 years. Breast cancer (Chapter 183) is the most common type of cancer and the second leading cause of cancer death in women. Studies indicate that many women significantly overestimate their personal risk for the disease. The lack of understanding of the cause of most breast cancers and the limitations of the imaging modalities used as screening tests have hampered efforts at breast cancer control. Data suggesting overdiagnosis of breast cancer, especially in women ages 40 to 50 years, has prompted an appreciation for the implications of screening mammography[11] and the virtue of shared decision making, especially in this age group. After decades of an increasing incidence of breast cancer in the United States, incidence rates have fallen in the past decade. The cause of this decline is not understood; reduced use of postmenopausal hormone therapy and recent declines in screening rates have been implicated. In women who are known carriers of the *BRCA1* and *BRCA2* mutations, estimates now can be made for age-specific risks of breast, ovarian, and contralateral breast cancer (see Chapter 183).

Lung cancer (Chapter 177) is now the leading cause of cancer death in women, and rates continue to rise, commensurate with the timeline for increasing rates of smoking in women. Most lung cancers are smoking related, although women are more likely than men to have lung cancers that are not tobacco related. Based on the results of randomized trials,[A7] guidelines recommend low-dose chest tomographic screening of women as well as men who have a greater than a 20 pack-year smoking history, who are current smokers, or who quit within the previous 15 years.[12] Nevertheless, smoking cessation (Chapter 363) continues to be the most effective strategy to prevent lung cancer and should be the focus of primary prevention.

Colorectal cancer (Chapter 179) has a similar incidence in both women and men. Screening is recommended beginning at age 45 years and continuing to age 75 years for both women and men[13] using colonoscopy every 10 years, sigmoidoscopy every 5 years, annual stool testing with a fecal immunochemical test or every 1 to 3 years with a DNA fecal immunochemical test. Rates of screening in women are similar to men, but neither reach Healthy People 2030 goals for this effective preventive screening.

Ovarian cancer (Chapter 184) is relatively rare, with about 21,000 cases in the United States, and its annual and incidence has declined in recent decades. However, mortality is high owing to its presentation at late stages in most cases. Lower abdominal or pelvic pain, urinary symptoms, and changes in bowel habits are nonspecific and common in many women, thereby limiting the ability to detect this cancer at an early stage. A screening pelvic examination is not useful in asymptomatic women, and no effective screening test has been shown to reduce mortality from ovarian cancer. As a result, screening of the general population is not recommended.[A8]

The greatest advance in cancer prevention is the development of vaccines against the most carcinogenic subtypes of human papillomavirus (HPV) associated with cervical cancer (Chapters 184 and 344)[A9] and anal cancer. Although concern of tacit approval of sexual activity among young adolescents has been cited by parents as a reason to delaying vaccination, evidence does not demonstrate this concern to be founded, and vaccination is recommended for girls at ages 11 to 12 years (Chapter 15). Pap test screening can be delayed until age 21 years. Cervical cancer screening is generally recommended with cervical cytology about every 3 years in women age 21 to 29 years and then either every 3 years with cytology alone or every 5 years with HPV testing in women ages 30 to 65 years.[14] Pap tests are not recommended for women after hysterectomy for nonmalignant indications or for women older than 65 years with adequate recent screening and no high-risk factors.

OSTEOPOROSIS

Osteoporotic fractures, especially of the wrist, hip, and vertebrae (Chapter 225), are major causes of disability, loss of independence, and mortality in older women. The prevention of osteoporosis begins at puberty and extends throughout adulthood by emphasizing the intake of calcium and vitamin D,

TABLE 219-2 PREFERRED MEDICATIONS FOR WOMEN OF REPRODUCTIVE POTENTIAL

COMMON CONDITIONS IN WOMEN OF REPRODUCTIVE POTENTIAL	ISSUES TO BE AWARE OF	PREFERRED MEDICATIONS OR GROUPS OF MEDICATIONS
Depression	Must consider effects of untreated depression on mother and infant	Avoid newer medications when older drugs with more information are available SSRIs are generally considered safe; fluoxetine has most safety data
Anxiety	Commonly associated with depression in women	Benzodiazepines generally considered safe
GERD	No data on harmful effects of either H_2-blockers or PPIs Misoprostol is contraindicated (can cause miscarriage, fetal death, congenital anomalies)	Calcium-containing antacids are first-line therapy H_2-blockers preferred over PPIs
Acne	Oral isotretinoin and topical tazarotene are contraindicated owing to congenital defects	Most other topical agents are considered classes B and C
Asthma	Extensive data on safety of common drug categories: benefit ratios far exceed risk in treating women	Glucocorticoid inhalers Systemic prednisone for flares Short- and long-acting bronchodilators
Seizure disorders	Difficult to separate effects of medication from effects of seizure on fetal development All agents associated with some increased risk for fetal abnormality (4-8%, compared with 1-2% in general population); valproate and phenobarbital have highest risks	Monotherapy at lowest doses recommended Avoid medication changes in first trimester Folate supplementation in preconception period
Hypertension (not preeclampsia)	ACE inhibitors and ARBs are contraindicated in pregnancy; possibly associated with cardiovascular and neurologic anomalies in first trimester; may cause abnormalities in renal hemodynamics in third trimester Most data suggest thiazide diuretics are safe if stable use before pregnancy	β-Blockers, especially labetalol, and methyldopa are first-line choices Calcium-channel blockers are also considered safe
Lipid disorders	Circulating lipid levels are elevated with pregnancy and breast-feeding	Except in very high risk women, no medications during pregnancy; ideally, stop statins before conception
Analgesics for fever and pain management	Controversy about whether NSAIDs slightly increase risk for miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Headache	Controversy about whether NSAIDs slightly increase risk for miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Diabetes	First-generation sulfonylureas contraindicated in pregnancy; may cause fetal hyperinsulinemia and birth defects	Conversion to insulin during planned preconception period Insulin, metformin, and glyburide preferred in women of childbearing potential
Autoimmune conditions	Must weigh benefits of immunosuppressive use against potential risks to both mother and infant Methotrexate is contraindicated in pregnancy because it induces miscarriage Limited data on TNF-alpha and IL-17 inhibitors; available data indicate minimal transfer of IgG across placenta and no known birth defects or premature birth	Prednisone generally considered safe in pregnancy Azathioprine, sulfasalazine, cyclosporine, and hydroxychloroquine generally preferred if required
Tobacco control	Cigarette smoking has known harmful effects on fetus In several randomized controlled trials, nicotine replacement was associated with reduced levels of nicotine and improved birth outcomes Bupropion has not shown adverse outcomes in several small randomized controlled trials	Try nonpharmacologic approaches to cessation first Short course of nicotine replacement likely better for fetus than smoking
Polycystic ovarian disease	Metformin can restore ovulatory cycles; use with contraception	
Bacterial infections	Tetracyclines accumulate in fetal bone and teeth Sulfa drugs may increase risk for neural tube defects with use in first trimester and kernicterus with use in third trimester Trimethoprim interferes with folic acid metabolism Streptomycin and kanamycin associated with bilateral deafness	Penicillins, cephalosporins, erythromycin, azithromycin considered safe

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; GERD = gastroesophageal reflux disease; IL-17 = interleukin-17; NSAID = nonsteroidal anti-inflammatory drug; PPI = proton pump inhibitor; SSRI = selective serotonin re-uptake inhibitor; TNF = tumor necrosis factor.

weight-bearing exercise, the avoidance of smoking, and moderate alcohol consumption. To maintain the structural strength of bone, women require a calcium intake of 1000 mg/day, increasing to 1300 mg in puberty and when breast-feeding and to 1200 mg after menopause. Vitamin D, which is a necessary element for the absorption of calcium (Chapter 199), is available through direct sun exposure, supplementation of milk (not most other dairy products), and supplementation of some juices. Epidemiologic data suggest widespread vitamin D deficiency in women in the United States, and screening for a single baseline serum 25-hydroxyvitamin D level can provide women with useful information about the adequacy of their diets and lifestyle. If the level is below 20 ng/mL, daily supplementation of vitamin D (600 IU, increased to 800 IU after age 70 years) is recommended for women.

Although no long-term outcome data exist on the benefits of dual-energy x-ray absorptiometry bone densitometry screening, most guidelines recommend such screening at age 65 years in women[15] but earlier at ages 50 to 65 years in women who have one or more risk factors (smoking, family history, body mass index < 22, or alcohol use). Long-term estrogen therapy is not recommended to prevent osteoporosis. Bisphosphonates are first-line therapy despite their associated risks of gastroesophageal erosions (with oral but not intravenous therapy) and rare but debilitating jaw osteonecrosis (Chapter 229). Raloxifene, a selective estrogen receptor modulator, can prevent osteoporosis while reducing the risk of breast cancer. Anabolic agents, including parathyroid hormone analogues, are recommended as secondary therapy for women who do not tolerate bisphosphonates, have

ongoing bone loss or fragility fractures despite bisphosphonates, or have severe osteoporosis.

COMMON CAUSES OF MORBIDITY IN WOMEN

OBESITY

Obesity rates continue to rise, and the prevalence of obesity is higher in women than men, especially among minority and low-income women (Chapter 201). In the United States, the rates of obesity in women have increased nearly 2.5-fold from 17% in 1976-1980 to almost 45% now. Reductions in caloric intake (Chapter 13) and increased exercise (Chapter 14) are key treatment strategies. Studies suggest that no single diet is superior to others, and many common diet strategies can reduce weight. Increasing activity during the course of one's daily routine is as effective as shorter intervals of more strenuous activity. The most effective programs include a combination of behavioral therapy, either individually or in groups, to address behavioral patterns of food intake, diet, and exercise. Weight loss targets of 1 to 2 lb/week and a total loss of up to 5 to 10% of body weight are realistic goals. Even modest changes in weight and modest increases in physical activity reduce morbidity and mortality on a population basis.

Exercise and diet changes are difficult for many people to achieve for a wide variety of reasons. The physical environment may not be conducive to physical activity owing to the sedentary nature of most workplaces, the lack of safe areas to exercise, and architectural design features, such as the lack of easy access to stairs instead of elevators. The use of prepared foods and the consumption of fast foods, which are high in calories and low in nutritional content, increase the risk for obesity.

There are currently no evidence-based interventions to support weight reduction in the setting of a brief office visit. Most guidelines focus on assessing BMI in all women and recommending weight reduction with diet restriction and exercise, including behavioral therapy to support these behavioral changes. Excessive postpartum weight retention (≥4.5 kg over prepregnancy weight at 6 to 12 months after delivery) also occurs disproportionately in minority and low-income women and is associated with similarly increased risk of complications, such as diabetes and cardiovascular disease. In contrast to current general obesity treatment guidelines that emphasize intensive, in-person interventions to affect lifestyle modification, management of postpartum weight retention is more effective using remote internet-based methods.[A10]

When behavioral interventions are inadequate, medical treatments include a pancreatic lipase inhibitor (orlistat), glucagon-like peptide 1 agonists (e.g., liraglutide and semaglutide), and combination therapy with bupropion-naltrexone or phentermine-topiramate (Chapter 201). However, pharmacotherapy should be used in conjunction with an exercise and diet program and not as sole therapy. For obese women with a BMI greater than 40 or with a BMI greater than 35 and major comorbid conditions (such as diabetes, sleep apnea, or osteoarthritis) despite behavioral and pharmacologic therapies, bariatric surgery (Chapter 201) is highly effective.

DEPRESSION

Major depression and other related disorders, including dysthymia, are more common in women (Chapter 402). Depression is a significant comorbidity in many chronic medical conditions and is also a disabling but treatable complication of the postpartum period. Somatic complaints are a common presentation of depressive disorders, so it is critical to consider depression as either a primary or a secondary diagnosis and to treat depression as part of the overall management plan.

Multiple short screening tools (see Table 361-6) have been developed to identify depression and are recommended for use in primary care settings, especially for women who are pregnant or postpartum. The treatment of dysthymia and depression includes psychotherapy (Table 362-4) and medications (Table 362-5).

ANXIETY DISORDERS

Anxiety disorders (Chapter 362) also are more common in women. They commonly coexist with depressive disorders. Anxiety disorders, including posttraumatic stress disorder, may be a consequence of violence against women, which often remains unidentified (Chapter 223). Benzodiazepines (Table 362-9) are safe and effective in trials for short-term use. Selective serotonin re-uptake inhibitors (Table 362-5) and cognitive behavioral therapies are effective for the long-term management of anxiety disorders.

OSTEOARTHRITIS

Osteoarthritis (Chapter 241) is one of the most common causes of morbidity and functional status limitation, especially as women age. Assessment of pain and functional status is at the core of management. Physical and occupational therapy to restore functional status is a critical component of care. Joint replacement (Chapter 255) should be considered and recommended when functional status interferes with activities of daily living and when supportive care and other symptom management strategies are ineffective.

SMOKING

Tobacco use, most commonly cigarette smoking, continues to be one of the major preventable causes of morbidity and mortality in women (Chapter 363). Despite progress in smoking cessation efforts, lower-income women and younger women continue to start smoking and fail to quit smoking at high rates. In the United States, girls currently initiate cigarette smoking at similar rates as boys in high school, thereby indicating that the challenges of smoking-related illness will continue in women.

Health care providers can achieve 1 to 2% reduction in smoking rates simply by asking all patients about their smoking status and making a brief statement encouraging smokers to quit. Further gains in smoking cessation are possible with targeted counseling, which involves assessing the patient's stage of readiness to change and providing counseling relevant to that stage.

Nicotine replacement therapy, bupropion, and varenicline are pharmacologic agents for smoking cessation (Chapter 363).[16] Limited data are available to assess the effectiveness of these therapies specifically in women, but nicotine replacement therapy is preferred during pregnancy, bupropion is recommended after the first trimester, and varenicline is not recommended for pregnant or breast-feeding women.

The use of electronic smoking devices has dramatically risen at similar rates in girls and boys of middle school and high school age. Although these devices may be helpful for smoking cessation, more commonly they serve as a gateway to cigarette smoking (Chapter 362) and expose users to the potential side effects of inhaled substances other than nicotine (Chapter 82).

ALCOHOL USE AND SUBSTANCE USE

Approximately 5% of women are dependent on alcohol (Chapter 364), but this dependence is under-recognized in clinical practice. It is well established that lower amounts of alcohol cause alcohol-related liver and other disease in women compared with men, and alcohol also increases the risk for breast cancer. Binge drinking (defined as four drinks or more at a sitting) by up to one in eight women who drink alcohol can lead to poor judgment and risks to personal safety. The approach to alcohol abuse is detailed in Chapter 364.

Women have lower rates of using substance abuse (Chapter 365) compared with men, and women account for only about half as many opioid-related deaths as men.[17] However, rates of opioid deaths continue to rise for women, especially for White women and especially deaths from overdoses involving synthetic opioids. All prescribing physicians must be aware of the risks of drug abuse. Approaches to preventing and treating drug abuse and dependence are described in detail in Chapters 365.

INCONTINENCE

Urinary incontinence (Chapter 115) is a frequently overlooked cause of major functional status limitations in middle-aged and older women. As many as half of affected women underreport this problem to their physicians and alter their lifestyles to adapt to the problem, including reducing fluid intake, avoiding activities that exacerbate the problem, and restricting travel where access to facilities is uncertain. Two broad categories of incontinence are stress incontinence and urge incontinence, but women commonly have aspects of both types. The distinction often can be made by a careful history, but urodynamic evaluation (Chapter 115) should be considered if the history does not clearly identify a cause. Stress incontinence is defined as leaking with increases in intra-abdominal pressure, such as occurs with sneezing or coughing as well as with running or even walking. The most common cause is laxity of the pelvic floor, often from childbirth. Kegel exercises are frequently recommended but are of limited value, so interventional procedures are often required (see Chapter 115).[18] Urge incontinence, described as detrusor muscle instability, results in the urge to void with low volumes. Both anticholinergic medications and bladder training (see Chapter 115) are effective.

HIV INFECTION

The major risk factors for HIV infection in women in the United States are heterosexual contact in about 90% of new cases and injection drug use in about 10%. Incidence rates remain lower in women than in men, with only about 20% of incident cases affecting women, in large part because male-to-male sexual contact continues to account for about two-thirds of cases in men (Chapter 353).

However, the absolute number of new infections from heterosexual contact is twice as high in women as it is in men. HIV continues to affect minority women disproportionately, with about 60% of prevalent U.S. cases affecting Black women.

Women with HIV/AIDS have poorer survival than men despite equivalent effectiveness of antiretroviral therapy (Chapter 357), perhaps because of poorer adherence, in part associated with caring for dependent children. Cervical (Chapter 184) and anal (Chapter 131) dysplasia and cancer are more common among women with HIV than women without it, so annual Pap tests are recommended for all women with HIV infection, even in the absence of positive HPV test results. Data currently are inadequate to support or refute anal screening. Prophylaxis (Chapter 356), treatment (Chapter 357), and management of complications (Chapters 358 and 359) of HIV/AIDS are discussed in detail in other chapters.

SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic provided an example of the intersection of lifespan stages and gender differences with environmental and behavioral exposures. Initial epidemiologic data were conflicted as to whether women were more or less likely to contract and die of SARS-CoV-2 infection. Some data linked severity of infection to androgen-responsive influences on the angiotensin converting enzyme receptor by which the virus binds to cells. Conversely, elderly women constitute a disproportionate share of the elderly population and of residents of skilled nursing facilities—groups that have higher SARS-CoV-2 mortality rates. In the United States, greater numbers of women work in health care settings, where initially inadequate personal protective equipment, not gender, drove differences in rates of disease and illness. Overall, based on the best-available data, the pandemic now appears to be sex-neutral.

REPRODUCTIVE HEALTH ISSUES

All providers caring for women with reproductive potential should consider the reproductive implications of preventive and therapeutic decisions. With half of all pregnancies in the United States unplanned, providers should routinely inquire about contraceptive practices and consider these in their care plans.

All primary care providers should be comfortable counseling patients about contraceptive choices and prescribing oral contraceptives (Chapter 220). The absolute contraindications to oral contraceptives are a personal history of cardiovascular disease, thromboembolic disease, migraine headache with aura, and gynecologic or breast cancer. A family history of cancer is not considered a contraindication; in fact, data suggest that the use of oral contraceptives decreases the risk for both endometrial and ovarian cancer. Smoking while using oral contraceptives increases the risk for thromboembolic events in all women but especially in those older than 30 years. Oral contraceptive use is considered safe in nonsmoking women until menopause. Preexisting hypertension is a relative contraindication to oral contraceptive use. Some women develop elevated blood pressures on oral contraceptives, so blood pressure should be monitored at 3 months after starting the drug and then at least annually.

Unsafe and self-managed abortion must be avoided.[19] Fortunately, medical abortion is safe for primary care providers to implement with appropriate backup. The evidence-based regimen is approved for use up to 63 days of gestation, using mifepristone 200 mg orally for a single dose, followed by 800 µg of misoprostol buccally 24 to 72 hours later. Recent studies have demonstrated its safety even as telemedicine with counseling but without observed administration. Success rates range from 94 to 98%. Rates of complications, which are similar to surgical abortion, include bleeding requiring blood transfusion in 0.05% of cases and rare infections, usually with non–evidence-based methods. Women should be counseled on side effects, including nausea and abdominal pain, with bleeding and expulsion of conception products usually following misoprostol. Providers should review local regulations: providers must register with the company to prescribe mifepristone. Some locales require that the original protocol be used and have additional regulations regarding counseling.

Providers should consider the reproductive implications of all chronic medications in women of reproductive potential (Table 219-2). Given that the teratogenic effects of medications may occur during the first trimester and before an initial obstetric assessment, the principle when choosing chronic medications for women during their reproductive years is to select those with the greatest safety profile during the first trimester of pregnancy.

The risk for untreated depression during pregnancy as well as the risks of postpartum depression to the woman and her infant are substantial,[20] so screening for depression is worthwhile. Antidepressant medications generally appear to be safe during pregnancy (Chapter 221), although selective serotonin reuptake inhibitors may increase the risk of postpartum hemorrhage. For women who wish to take no medication during pregnancy, the recommendation is gradually to reduce the dosage over the course of several weeks. In the postpartum period, close surveillance is important for early detection and treatment with adequate and even increased doses of antidepressant medication to prevent the worsening of depression.

220 CONTRACEPTION

BEVERLY WINIKOFF AND DANIEL GROSSMAN

CONTRACEPTIVE USE

Contraception enables people to avoid unwanted fertility by preventing pregnancy.[1] Methods can be classified in many ways. Some classification schemes distinguish among mechanisms (e.g., barriers to the encounter of sperm and ovum versus methods that prevent ovulation); other categories emphasize the timing of use (at the time of intercourse vs. ongoing); still other classifications focus on the permanence of the method (sterilization, which is intended as a permanent method; long-acting methods that persist for years; and short-term methods that depend on the periodic behavior of the user, such as every day or at every exposure to pregnancy). Each contraceptive method has advantages and disadvantages,[2] which should be thoroughly explained so that the individual or couple will choose the most acceptable method to suit their lifestyles and will use it most effectively.[3] Because medical contraindications to individual methods are uncommon among young women, the choice among contraceptive methods usually depends mostly on the user's preferences.

In a recent United States survey, about 65% of women of reproductive age (15 to 44 years old) were using a contraceptive method.[4] Among women not using contraception, some women were not currently sexually active (17%) or were currently pregnant, postpartum, or trying to conceive (8%). Only about 7% of women were sexually active in the prior 3 months but were not using a method of contraception, and about 3% were not using contraception for other reasons (e.g., women with nonsurgical sterility). In the United States, approximately 45% of pregnancies are unintended, that is, mistimed or unwanted.

However, the absolute number of new infections from heterosexual contact is twice as high in women as it is in men. HIV continues to affect minority women disproportionately, with about 60% of prevalent U.S. cases affecting Black women.

Women with HIV/AIDS have poorer survival than men despite equivalent effectiveness of antiretroviral therapy (Chapter 357), perhaps because of poorer adherence, in part associated with caring for dependent children. Cervical (Chapter 184) and anal (Chapter 131) dysplasia and cancer are more common among women with HIV than women without it, so annual Pap tests are recommended for all women with HIV infection, even in the absence of positive HPV test results. Data currently are inadequate to support or refute anal screening. Prophylaxis (Chapter 356), treatment (Chapter 357), and management of complications (Chapters 358 and 359) of HIV/AIDS are discussed in detail in other chapters.

SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic provided an example of the intersection of lifespan stages and gender differences with environmental and behavioral exposures. Initial epidemiologic data were conflicted as to whether women were more or less likely to contract and die of SARS-CoV-2 infection. Some data linked severity of infection to androgen-responsive influences on the angiotensin converting enzyme receptor by which the virus binds to cells. Conversely, elderly women constitute a disproportionate share of the elderly population and of residents of skilled nursing facilities—groups that have higher SARS-CoV-2 mortality rates. In the United States, greater numbers of women work in health care settings, where initially inadequate personal protective equipment, not gender, drove differences in rates of disease and illness. Overall, based on the best-available data, the pandemic now appears to be sex-neutral.

REPRODUCTIVE HEALTH ISSUES

All providers caring for women with reproductive potential should consider the reproductive implications of preventive and therapeutic decisions. With half of all pregnancies in the United States unplanned, providers should routinely inquire about contraceptive practices and consider these in their care plans.

All primary care providers should be comfortable counseling patients about contraceptive choices and prescribing oral contraceptives (Chapter 220). The absolute contraindications to oral contraceptives are a personal history of cardiovascular disease, thromboembolic disease, migraine headache with aura, and gynecologic or breast cancer. A family history of cancer is not considered a contraindication; in fact, data suggest that the use of oral contraceptives decreases the risk for both endometrial and ovarian cancer. Smoking while using oral contraceptives increases the risk for thromboembolic events in all women but especially in those older than 30 years. Oral contraceptive use is considered safe in nonsmoking women until menopause. Preexisting hypertension is a relative contraindication to oral contraceptive use. Some women develop elevated blood pressures on oral contraceptives, so blood pressure should be monitored at 3 months after starting the drug and then at least annually.

Unsafe and self-managed abortion must be avoided.[19] Fortunately, medical abortion is safe for primary care providers to implement with appropriate backup. The evidence-based regimen is approved for use up to 63 days of gestation, using mifepristone 200 mg orally for a single dose, followed by 800 µg of misoprostol buccally 24 to 72 hours later. Recent studies have demonstrated its safety even as telemedicine with counseling but without observed administration. Success rates range from 94 to 98%. Rates of complications, which are similar to surgical abortion, include bleeding requiring blood transfusion in 0.05% of cases and rare infections, usually with non–evidence-based methods. Women should be counseled on side effects, including nausea and abdominal pain, with bleeding and expulsion of conception products usually following misoprostol. Providers should review local regulations: providers must register with the company to prescribe mifepristone. Some locales require that the original protocol be used and have additional regulations regarding counseling.

Providers should consider the reproductive implications of all chronic medications in women of reproductive potential (Table 219-2). Given that the teratogenic effects of medications may occur during the first trimester and before an initial obstetric assessment, the principle when choosing chronic medications for women during their reproductive years is to select those with the greatest safety profile during the first trimester of pregnancy.

The risk for untreated depression during pregnancy as well as the risks of postpartum depression to the woman and her infant are substantial,[20] so screening for depression is worthwhile. Antidepressant medications generally appear to be safe during pregnancy (Chapter 221), although selective serotonin reuptake inhibitors may increase the risk of postpartum hemorrhage. For women who wish to take no medication during pregnancy, the recommendation is gradually to reduce the dosage over the course of several weeks. In the postpartum period, close surveillance is important for early detection and treatment with adequate and even increased doses of antidepressant medication to prevent the worsening of depression.

220 CONTRACEPTION

BEVERLY WINIKOFF AND DANIEL GROSSMAN

CONTRACEPTIVE USE

Contraception enables people to avoid unwanted fertility by preventing pregnancy.[1] Methods can be classified in many ways. Some classification schemes distinguish among mechanisms (e.g., barriers to the encounter of sperm and ovum versus methods that prevent ovulation); other categories emphasize the timing of use (at the time of intercourse vs. ongoing); still other classifications focus on the permanence of the method (sterilization, which is intended as a permanent method; long-acting methods that persist for years; and short-term methods that depend on the periodic behavior of the user, such as every day or at every exposure to pregnancy). Each contraceptive method has advantages and disadvantages,[2] which should be thoroughly explained so that the individual or couple will choose the most acceptable method to suit their lifestyles and will use it most effectively.[3] Because medical contraindications to individual methods are uncommon among young women, the choice among contraceptive methods usually depends mostly on the user's preferences.

In a recent United States survey, about 65% of women of reproductive age (15 to 44 years old) were using a contraceptive method.[4] Among women not using contraception, some women were not currently sexually active (17%) or were currently pregnant, postpartum, or trying to conceive (8%). Only about 7% of women were sexually active in the prior 3 months but were not using a method of contraception, and about 3% were not using contraception for other reasons (e.g., women with nonsurgical sterility). In the United States, approximately 45% of pregnancies are unintended, that is, mistimed or unwanted.

ABSTRACT

Contraception enables people to avoid unwanted fertility by preventing pregnancy. In the United States, about 65% of women of reproductive age are using a method of contraception. However, nearly half of U.S. pregnancies are unintended, and more than half of such pregnancies occur to women not practicing contraception. The most common methods of pregnancy prevention are oral contraceptives and female sterilization. Use of long-acting reversible contraception has increased rapidly in recent years. Other contraceptive methods include male condoms, male sterilization, injectable progestin, and contraceptive rings or patches. Approximately 3% of women of reproductive age report using withdrawal. "Perfect use" and "typical use" are different metrics to describe the protection afforded by different contraceptives under varied circumstances. Perfect use refers to use of the method as intended/instructed and covering all acts of exposure to pregnancy. Typical use, on the other hand, is a measure of a method's effectiveness when used as people actually use them. The U.S. Centers for Disease Control and Prevention has developed evidence-based Medical Eligibility Criteria (MEC) for contraceptive use. This chapter reviews each contraceptive method and its mechanism of action, efficacy, contraindications, advantages, disadvantages, and instructions for use.

KEYWORDS

contraception
fertility
hormonal
intrauterine device
implant
sterilization

In the United States in 2017 to 2019, the most common methods of pregnancy prevention were female sterilization (18%) and oral contraceptives (OCs or "the pill;" 14%). Use of long-acting reversible contraception (e.g., intrauterine device [IUD] and implants) has increased rapidly in recent years, with about 10% of women reporting use of such methods. Other reported methods include male condoms (8%), male sterilization (6%), injectable progestin, and contraceptive ring or patch (total: 3%). All other methods accounted for 6% of contraceptive use. In the United States, the likelihood of using contraception varies rather little by educational status. However, the choice of method is related to educational attainment, with sterilization chosen more frequently by less-educated women and oral contraceptives more frequently chosen by more educated women. Unsurprisingly, female sterilization is mostly chosen by older women.

UNINTENDED PREGNANCY AND CONTRACEPTIVE USE

In the United States, approximately 45% of pregnancies are estimated to be unintended. Data indicate that 95% of unintended pregnancies occur among women who do not use contraception (54%) or use it inconsistently (41%). The highest unintended pregnancy rates are in women ages 18 to 24 years, women living on low incomes, and women who are unmarried but living with a partner. Factors associated with nonuse of contraception or gaps in its use include side effects (both experienced and feared), not liking a method, personal or religious reasons, and barriers to access, including high cost and difficulty obtaining the method.

Although there is certainly a need to develop new contraceptive methods with fewer side effects, as well as methods for men,[5] much more could be done to improve access to the full range of existing methods at low or no cost. People have different preferences regarding contraceptive methods, and matching those preferences with the most appropriate method is a critical role of the practicing physician. Physicians should address the contraceptive needs and preferences of all of their patients, including those who are transgender and gender nonconforming (Chapter 215).[6]

PERFECT USE VERSUS TYPICAL USE

"Perfect use" and "typical use" characterize different aspects of the effectiveness of the various contraceptive methods. *Perfect use* refers to use of the method as intended and covering all acts of exposure to pregnancy. For user-dependent methods such as oral pills or condoms, for example, this measure can be applied only to situations in which the user reliably uses the method every day or at every act of intercourse. Perfect use is a measure of the maximum possible efficacy of the method. *Typical use,* by comparison, is a measure of the effectiveness of a method as used by the people who actually use it. Typical use rates may be considerably lower than perfect use rates, especially if the method must be used at every act of intercourse or can be used in ways other than as intended. Different contraceptive methods have varying failure rates under conditions of perfect use and typical use (Table 220-1). The actual use (typical) failure rates of most contraceptive methods can be divided into three main classes of effectiveness (Fig. 220-1). Pregnancies conceived while using contraceptive methods do not have an increased risk of birth defects.

Methods used at the time of coitus have higher failure rates than oral contraceptives, implants, injections, IUDs, and sterilization. IUDs, implants, and sterilization have lower failure rates than oral contraceptives, patches, and injections, because they act over a longer period of time, and a user need not do anything else during their duration of effectiveness.

Cumulative failure rates for long-acting methods are low. The effectiveness of long-acting reversible contraception is superior to that of contraceptive pills, patch, or ring, and it is not altered in adolescents and young women. The cumulative failure rates of all types of tubal sterilization are 1.31% during the first 5 years after the procedure and 1.85% after 10 years; rates are higher for tubal fulguration and lower for segmental resection. The cumulative pregnancy rate for 5 years' use of the levonorgestrel-releasing IUD is 0.5%, and for 10 years' use of the copper T380 IUD, it is 1.7%.

CONTRAINDICATIONS, RISKS, AND BENEFITS

Most contraceptives can be used safely by most people, but some conditions or concomitant medications are considered contraindications to certain methods. The U.S. Centers for Disease Control and Prevention has developed evidence-based Medical Eligibility Criteria (MEC) for contraceptive use, based on a similar document developed by the WHO (https://www.cdc.gov/reproductivehealth/contraception/mmwr/mec/summary.html). For conditions that represent relative contraindications, it is important to recognize that pregnancy also may be risky, and if the method is the best choice to avoid an unintended pregnancy, it may be worth the risk.

Many contraceptive methods have additional benefits aside from prevention of unintended pregnancy. One of the most significant noncontraceptive benefits is the reduced risk of sexually transmitted infections, including human immunodeficiency virus (HIV; Chapter 356), associated with the use of male and female condoms. Another important contraceptive benefit is the reduction in dysmenorrhea and menorrhagia (Chapter 218) associated with the use of combined hormonal contraception; these methods are also associated with a reduced risk of ovarian and endometrial cancer (Chapter 184).

TYPES OF CONTRACEPTIVES

BEHAVIORAL METHODS

Methods that rely on the cyclic infertility of certain times in the menstrual cycle (Chapter 218) or life cycle are often called "natural" methods. These methods are not really more natural than other methods; rather, they rely more on a couple's behavior rather than on any specific external technology to create a state of low fertility potential. Because male sperm can live for only 5 days in the female genital tract and because female ova have a lifespan of only about 24 hours, the window for fertilization is only 5 to 6 days each month. If couples avoid unprotected intercourse on those 5 to 6 days, the potential for pregnancy is markedly reduced. The calendar method counts the days of the cycle to predict fertile and infertile days, and the symptothermal method relies on the calendar plus the biologic signals of impending ovulation (changes in vaginal mucus) and of ovulation itself (rise in basal body temperature) to enhance prediction of "safe" days for intercourse. The U.S. Food and Drug Administration (FDA) recently approved a mobile application called Natural Cycles (https://www.naturalcycles.com/) to assist users of the fertility-awareness contraceptive method.

In the postpartum period, breast-feeding also suppresses ovulation, lowers fertility, and is considered another natural method of contraception. Exclusive breast-feeding during the first 6 months after a birth provides a good level of protection against pregnancy. However, once a baby is older than 6 months or if foods other than breast milk become part of the infant's diet, then a woman is at much higher risk for ovulation and possible pregnancy.

Withdrawal, or coitus interruptus, occurs when the penis is removed from the vagina before ejaculation. This commonly used method is reported as having been used at least once by up to 60% of women. Although this method can be effective with perfect use, with a pregnancy rate of only 4% in the first year of use, failure is much more common with typical use. In one U.S. study among women ages 15 to 24 years who used withdrawal as their primary method, 21% experienced an unintended pregnancy over a 4-year period, a pregnancy rate that was significantly higher than the rate among users of other contraceptive methods.

BARRIERS

Barrier methods impose a chemical or physical barrier between ovum and sperm so that fertilization is not possible. Barrier methods include spermicides, diaphragm, and male and female condoms, among others.

Spermicides

Most spermicidal agents contain a surfactant (in U.S. products this chemical is nonoxynol-9) that immobilizes or kills sperm on contact. The spermicidal products are available in foams, creams, and vaginal suppositories that must be placed into the vagina before each coital act—and reapplied even if coital acts follow immediately after each other. The typical-use effectiveness of surfactant-based spermicides as a sole contraceptive is among the lowest of modern methods (about 28% of women using the method report an unintended pregnancy during 1 year of use). Another contraceptive vaginal gel (Phexxi) contains L-lactic acid, citric acid, and potassium bitartrate to maintain a low, spermicidal vaginal pH; its use is associated with a seven-cycle pregnancy rate of 14%, and almost 50% of users have an adverse event, including vulvovaginal burning or itching.[7]

Diaphragm

A diaphragm is a dome-shaped latex or silicone device with a flexible rim that seals off the upper genital tract from contact with deposited semen. Diaphragms are usually used with a spermicide that is applied inside and around the rim. Traditional diaphragms must be fitted by a health care provider using the largest size that does not cause discomfort or undue pressure on the vagina. A silicone diaphragm (Caya) is available in a single size that fits women who are

*Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides and the diaphragm are taken from the 1995 National Survey Growth (NSFG) and corrected for underreporting of abortion; estimates for fertility awareness-based methods, withdrawal, the male condom, the pill, and Depo-Provera are taken from the 1995-2002 NSFG corrected for underreporting of abortion.

†Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

‡Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

§The percentages who become pregnant in the second and third columns are based on data from populations in which contraception is not used and from women who cease using contraception to become pregnant. Among such populations, approximately 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women not relying on reversible methods of contraception if they abandoned contraception altogether.

¤Foams, creams, gels, vaginal suppositories, and vaginal film.

¶The ovulation and 2-day methods are based on evaluation of cervical mucus. The standard-days method avoids intercourse on cycle days 8 to 19. The symptothermal method is a double-check method based on evaluation of cervical mucus to determine the first fertile day and evaluation of cervical mucus and temperature to determine the last fertile day.

**Without spermicides.

††With spermicidal cream or jelly.

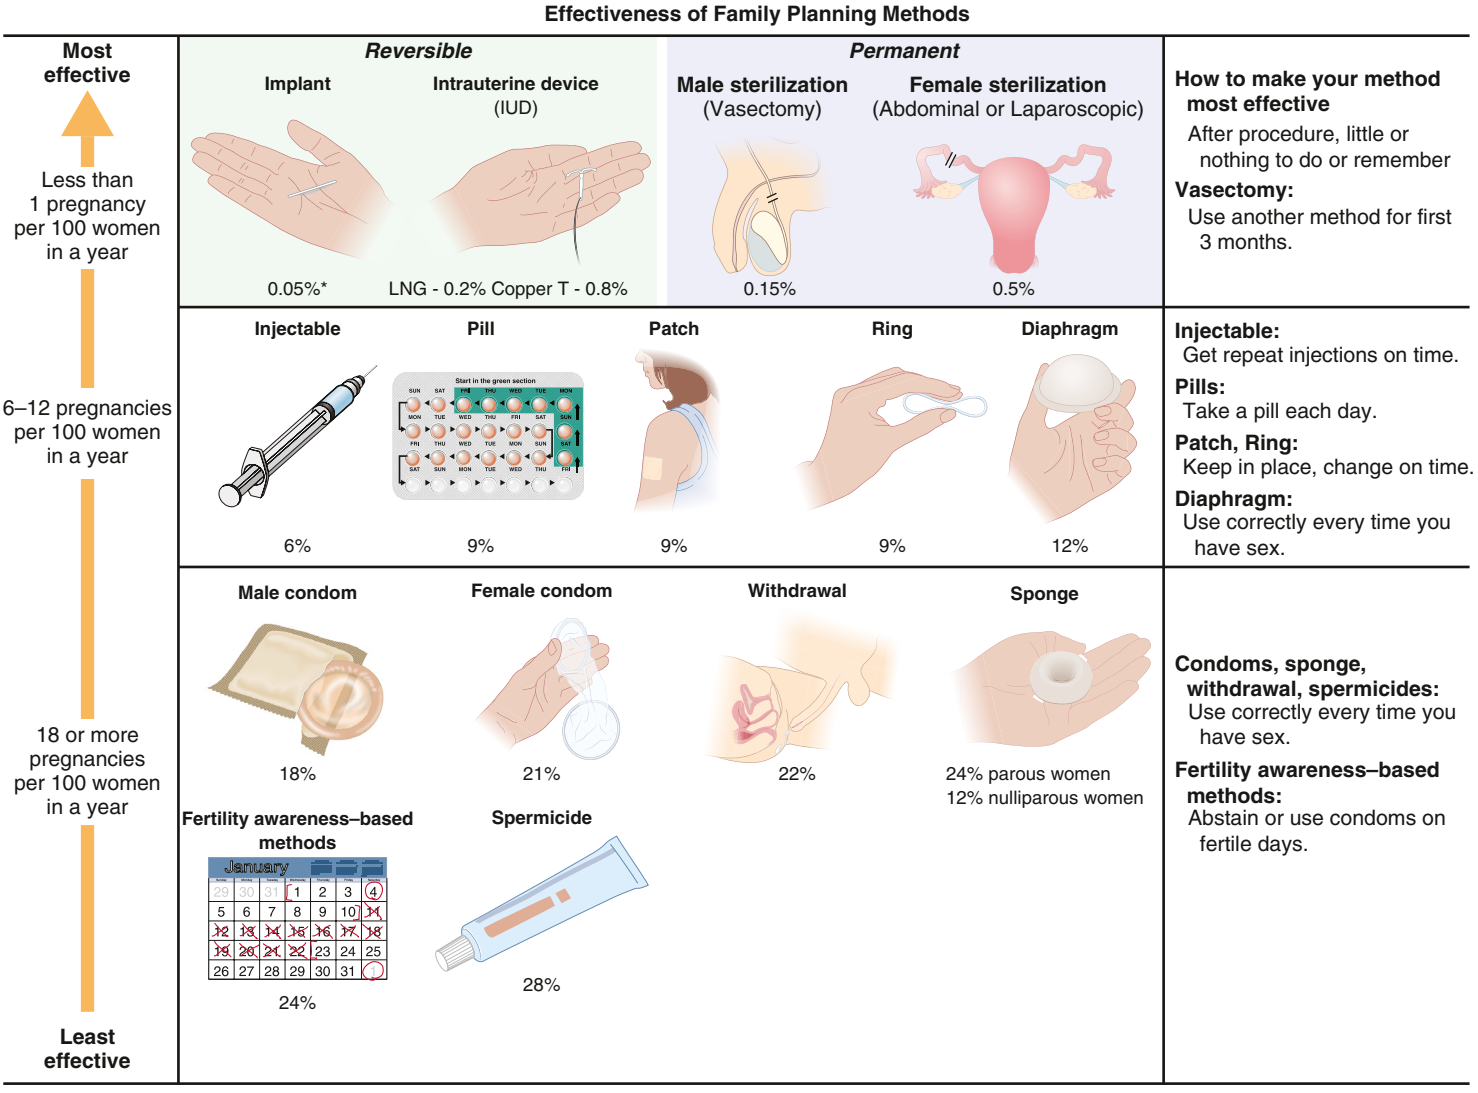
sized between 65 and 80 mm, which is the majority of women. All diaphragms must be inserted before every act of intercourse and should be left in place for 6 hours after intercourse (but not longer than 24 hours, because it may cause ulceration of the vaginal epithelium). In actual use, all diaphragms are equally effective,[A1] more effective than other barrier methods (12% unintended pregnancy rate in first year of use), and provide contraceptive protection that is almost as effective as oral contraceptives in actual use. The ideal diaphragm size for any one woman may change after a birth, miscarriage or abortion after 14 weeks, abdominal or pelvic surgery, or a substantial change in weight. The diaphragm may provide some protection against gonorrhea and chlamydia infection, but not against HIV or herpes simplex. A condom is recommended if infection is a concern. Diaphragm users have an increased risk for urinary tract infection.

Male Condom

The male condom, also called an external condom, is one of the oldest contraceptives known. It is safe, easy to use, and widely available. The modern version is a stretchy latex or plastic sheath that fits over the erect penis and captures the man's ejaculate during intercourse. It is the most effective way to prevent transmission of infections (including HIV) during sex and can be used during vaginal, oral, or anal intercourse. However, natural membrane condoms (made from sheep intestine) do not prevent sexually transmitted infections. Condoms can be used for protection against infection even if another method is used for protection against pregnancy. If the condom is used alone for contraception, in typical use about 18% of women will experience an unintended pregnancy in 1 year. For optimum protection, a new condom must be used at every sex act, and the man must actively participate in the process. Lubricants containing oil-based products may weaken latex condoms and should not be used with them; water-based lubricants are safe to use. The male condom causes no side effects except possible irritation or allergy.

Female Condom

The female condom, also called an internal condom, is a soft, loose-fitting prelubricated pouch with two flexible polyurethane rings, one at each end. The smaller ring at the closed end is inserted well into the vagina, thereby creating a barrier to sperm. The larger ring remains outside the vagina, thereby



Condoms should always be used to reduce the risk for sexually transmitted infections.

Other Methods of Contraceptions

Lactational Amenorrhea Method: LAM is a highly effective, temporary method of contraception.

Emergency contraception: Emergency contraceptive pills or a copper IUD after unprotected intercourse substantially reduces risk for pregnancy.

FIGURE 220-1. Detailed chart of the effectiveness of family planning methods with instructions for subjects. *The percentages indicate the number out of every 100 women who experienced an unintended pregnancy within the first year of typical use of each contraceptive method. LNG = levonorgestrel. (Adapted from World Health Organization [WHO] Department of Reproductive Health and Research, Johns Hopkins Bloomberg School of Public Health/Center for Communication Programs [CCP], Knowledge for Health Project. *Family Planning: A Global Handbook for Providers*. 2011 updates. Baltimore, Geneva: CCP and WHO; 2011, and Trussell J. Contraceptive failure in the United States. *Contraception*. 2011;83:397-404.)

covering the vulva and providing additional protection. The female condom can be inserted before beginning sexual activity and left in place for a longer time than the male condom after ejaculation occurs. Because polyurethane is stronger than the latex used in most male condoms, the female condom is less likely to rupture. Both polyurethane and latex prevent viral transmission and should reduce the risk for acquiring HIV infection.

HORMONAL (STEROIDAL) CONTRACEPTION

Hormones (or derivatives/analogues of hormones) that occur naturally in the female reproductive cycle can alter the reproductive system so that ovulation does not occur and/or so that physical factors (e.g., mucus production, tubal motility, and endometrial thickness) that enhance the probability of fertilization or implantation are altered. All modern hormonal formulations are made from synthetic steroids. The hormones are either a combination of an estrogen and a progestin or a progestin alone. Oral contraceptives are the most commonly used of these methods.

Oral contraceptives do not cause permanent infertility. After discontinuation, the rate of return of fertility is slightly lower, however, for users of oral contraceptives than for users of barrier methods but faster than for users of Depo-Provera. Obesity and a higher body mass index may attenuate the efficacy of combined hormonal contraceptives, but the absolute reduction in efficacy, if any, is small.

From the user's point of view, the main differences among these contraceptives are route of administration, length of action, how much attention the user needs to pay to the administration of the drug, and side effects. All these methods are very effective, and, if used consistently, result in very low pregnancy rates. Even with typical use, they are among the more effective methods, although, with the exception of the implants, they are less effective than sterilization or the IUD.

Currently, the search for male hormonal contraceptives has not yielded methods with sufficient efficacy and safety. Nonhormonal medications are also being investigated but are not currently available.[8]

Because hormonal contraceptives require a prescription in the United States and many other countries, some women may experience obstacles to initiating or continuing their use. Strategies to improve access to these methods include the use of telemedicine and pharmacist-initiated provision.[9] Whether these products should be available without a prescription is currently under debate, guided by the weighing of their benefits but also their risks.

Oral Contraceptives

The three major types of oral contraceptive formulations are fixed-dose combinations, phasic combinations, and daily progestin. The combination formulations, which are the most prescribed and most widely used, consist

TABLE 220-2 COMMONLY USED ORAL CONTRACEPTIVE FORMULATIONS

ESTROGEN	PROGESTIN	NOTES
MONOPHASIC REGIMENS		
Ethinyl estradiol 20 μg	Levonorgestrel 0.09 mg Levonorgestrel 0.1 mg Norethindrone acetate 1 mg Drospirenone 3 mg	See caution regarding serum potassium level*
Ethinyl estradiol 30 μg	Levonorgestrel 0.15 mg Norgestrel 0.3 mg Norethindrone acetate 1.5 mg Desogestrel 0.15 mg Drospirenone 3 mg	See caution regarding serum potassium level*
Ethinyl estradiol 35 μg	Norethindrone 0.4 mg Norethindrone 0.5 mg Norethindrone 1 mg Norgestimate 0.25 mg Ethynodiol diacetate 1 mg	
Estetrol 14.2 mg	Drospirenone 3 mg	See caution regarding serum potassium level*
MULTIPHASIC REGIMENS (DOSAGES VARY BY WEEK)		
Estradiol valerate 1-3 mg	Dienogest 0-3 mg	
Ethinyl estradiol 10 μg	Norethindrone acetate 0-1 mg	
Ethinyl estradiol 0-20 μg	Desogestrel 0-0.15 mg	
Ethinyl estradiol 20-35 μg	Norethindrone acetate 1 mg	
Ethinyl estradiol 25 μg	Norgestimate 0.18-0.25 mg Desogestrel 0.1-0.15 mg	
Ethinyl estradiol 30-40 μg	Levonorgestrel 0.05-0.125 mg	
Ethinyl estradiol 35 μg	Norgestimate 0.18-0.25 mg Norethindrone 0.5-1 mg	
EXTENDED 91-DAY REGIMENS		
Ethinyl estradiol 20 μg	Levonorgestrel 0.1 mg	84 days of the combination and 7 days of ethinyl estradiol 10 μg only
Ethinyl estradiol 20-30 μg	Levonorgestrel 0.15 mg	84 days of the combination and 7 days of ethinyl estradiol 10 μg only
Ethinyl estradiol 30 μg	Levonorgestrel 0.15 mg	84 days of the combination and 7 days of ethinyl estradiol 10 μg only
Ethinyl estradiol 30 μg	Levonorgestrel 0.15 mg	84 days of the combination and 7 days of placebo tablets
PROGESTIN-ONLY REGIMENS		
None	Norethindrone 0.35 mg	
None	Norgestrel 0.075 mg	
None	Drospirenone 4 mg	See caution regarding serum potassium level*

*Should not be used in patients with conditions that predispose to hyperkalemia. People receiving daily, long-term treatment for chronic conditions or diseases with medications that may increase the serum potassium level should have their serum potassium level checked during the first treatment cycle or when such medications are started.

of tablets containing both an estrogen and a progestin (Table 220-2), usually given continuously for 3 weeks. Generally, no active hormonal pills are taken during the fourth week. A few formulations provide active tablets for 24 days, with 4 days of inactive tablets. Other formulations provide active tablets for 84 days followed by 7 days without active tablets or with a low dose of estrogen to allow withdrawal bleeding.

The endometrium usually begins to slough 1 to 3 days after steroid ingestion is stopped, thereby causing withdrawal bleeding that usually persists for 3 to 4 days (and which users interpret as menstrual bleeding). The uterine blood loss with oral contraceptive use averages about 25 mL per cycle, which is less than the 35 mL average for ovulatory cycles.

Three estrogens (ethinyl estradiol, estradiol valerate, and estetrol) are used in combined oral contraceptives. These estrogens are combined in the pills with a progestin, such as levonorgestrel or norethindrone. Another progestin, drospirenone, is structurally related to spironolactone and has been formulated into an oral contraceptive. In the United States, there are also daily progestin-only formulations that include norethindrone, norgestrel, or drospirenone; levonorgestrel and desogestrel progestin-only pills are approved in other countries.

Combined oral contraceptives, which contain both estrogen and progestin, consistently inhibit the midcycle gonadotropin surge and thereby prevent ovulation. The progestin-only formulations generally have a lower dose of progestin than the combined agents and do not consistently inhibit ovulation, even though they are ingested every day. Progestin-only pills containing desogestrel appear to more consistently inhibit ovulation than other progestin-only formulations. Both combined oral contraceptives and progestin-only formulations also act on the cervical mucus and tubal motility to interfere with sperm transport. Progestins also alter the endometrium so that if fertilization occurs, implantation may be prevented. For contraceptive effectiveness to be maintained with the combination formulations, the pill-free interval must be limited to no more than 7 days, a limit that is reinforced by the inclusion of placebo pills in the packet for the hormone-free days. Continuous or extended cycle combined oral contraceptives are an equally safe option for individuals who prefer them.

Side Effects

The synthetic steroids in oral contraceptives can cause a range of side effects that are directly related to the dosage and potency of the steroids in the formulation. The most frequent symptoms produced by the estrogen component include nausea, breast tenderness, and fluid retention (bloating). The progestins can produce weight gain, acne, and depression. Because estrogens decrease sebum production, women who have acne may experience improvement in their symptoms. Insufficient estrogen, too much progestin, or a combination of both may result in unscheduled (breakthrough) bleeding, a problem that is more common with formulations containing 20 μg of estrogen than with formulations containing 30 to 35 μg and that is increased in women who also smoke cigarettes. Shortening the pill-free interval to 3 or 4 days may decrease the incidence of unscheduled bleeding with low-estrogen formulations.

The synthetic estrogens used in oral contraceptives cause an increase in the hepatic production of factors V, VIII, and X and fibrinogen, thereby potentially increasing the risk of thrombosis (see later) and an increase in angiotensinogen levels, which may elevate blood pressure in some users. Blood pressure should be followed in all users of combined oral contraceptives. Patients who develop hypertension should be switched to a non–estrogen-containing method. Progestins do not affect protein synthesis except to reduce levels of sex hormone–binding globulin.

Complications and Risk Factors

Thrombosis

Women of reproductive age who are not pregnant or using oral contraceptives experience venous thrombosis (Chapter 68) at a rate of 1.9 to 3.7 per 10,000 woman-years, but the 3.5-fold increased relative risk of venous thromboembolism with combined estrogen/progesterone oral contraceptives is still less than the risk of thrombosis associated with pregnancy.[10] In the presence of an inherited hypercoagulable state (Chapter 67), the risk for venous thrombosis is increased several-fold. Screening for coagulation deficiencies before women are started on oral contraceptives is not recommended unless the individual has a personal or significant family history of thrombotic events. Women with known inherited or acquired thrombogenic conditions should not use estrogen-containing steroid contraceptives in pills, rings, or patches, because each of these agents has thrombogenic effects. Observational studies suggest there may be a small increase in the risk for venous thromboembolism in individuals who use oral contraceptives with the newer, less androgenic progestins than for agents that contain levonorgestrel with the same amount of estrogen.

Myocardial Infarction and Stroke

Myocardial infarction (Chapters 57 and 58) is rare among women of reproductive age, with a rate of about 10 per 100,000 person-years. Epidemiologic

studies indicate that use of low-dose oral contraceptives by nonsmoking women without hypertension is not associated with a significantly increased incidence of myocardial infarction or stroke. Combination oral contraceptives should not be prescribed to women ages 35 years or older who smoke cigarettes.

Cancers of the Reproductive System

Among women who use or have used oral contraceptives, the risk of breast cancer (Chapter 183) is increased by 20% compared with women who never used them.[11] The risk increases with a longer duration of use, but the absolute increases are small.[12]

For invasive cervical cancer or cervical intraepithelial neoplasia (Chapter 184), most well-controlled studies indicate no change in risk associated with the use of oral contraceptives. For endometrial cancer, data suggest that the use of oral contraceptives has a protective effect and that the decrease in risk persists for many years after oral contraceptives are discontinued. This protective effect, which also is related to duration of use, increases from a 20% reduction with 1 year of use to a 60% reduction with 4 years of use. The level of protection declines with time after use is stopped.

Oral contraceptives also reduce the risk of developing epithelial ovarian cancer, as well as cancers with low malignant potential. The magnitude of the decrease in risk, which is directly related to the duration of the use of oral contraceptives, increases from about a 40% reduction with 4 years of use to about a 60% reduction with 12 years of use. The protective effect continues for at least 20 years after the use of oral contraceptives ceases. As with endometrial cancer, the protective effect occurs only in women of low parity (fewer than four), who are at greatest risk for this type of cancer.

Data also suggest that oral contraceptives reduce the risk for development of colorectal cancer (Chapter 179) by about 20%, and the risk of hematologic malignancies may be lower as well. Oral contraceptives do not increase risk for liver cancer (Chapter 181), and current formulations also do not increase the risk of developing a benign hepatocellular adenoma. Use of oral contraceptives does not increase the risk for developing malignant melanoma or prolactin-secreting pituitary adenomas.

Contraindications

Oral contraceptives can be prescribed for most women of reproductive age, but conditions that are considered absolute contraindications to use of combined hormonal contraceptives (category 4), include smoking 15 cigarettes or more per day at age 35 or older, severe hypertension, migraine headaches with an aura, and a history of atherosclerosis or venous thrombosis (see Table 220-3), among others.[13]

Management of Oral Contraceptive Therapy

If a healthy woman has no contraindications to the use of oral contraceptives, neither a pelvic nor breast examination nor any laboratory tests are required before prescribing them, and it is reasonable to prescribe oral contraceptives during a telehealth visit. Starting pills on the day of the visit is associated with better long-term adherence. There is no reason to discontinue oral contraceptive use unless pregnancy is desired. Because of their many health benefits, including the reduction in risk for endometrial and ovarian cancer and the induction of regular cyclic uterine bleeding, oral contraceptives use can be continued until menopause.

Some drugs can interfere clinically with the action of oral contraceptives by inducing liver enzymes that convert the steroids to more polar and less biologically active metabolites and cause breakthrough bleeding. These drugs include certain anticonvulsants and rifampin, among others. Use of oral contraceptives together with fosamprenavir may result in decreased effectiveness of the antiretroviral (see Table 220-3).

A common clinical question is what to do if a pill is missed. The standard advice for combined oral contraceptives is to take the first missed pill as soon as possible and take the remaining pills at the usual time, even if it means taking two pills in one day (discarding any additional missed pills). If two or more pills are missed, the most recent missed pill should be taken as soon as possible, and the remaining pills should be taken at the usual time, even if two or more pills must be taken on the same day; reliable contraception will require an additional technique (e.g., condoms) or the avoidance of sexual intercourse until pills have been taken for at least 7 consecutive days. If pills were missed in the last week of hormonal pills (third week of cycle), the hormone-free interval should be omitted, and the new pack should be started the next day; emergency contraception should be considered. Vomiting and diarrhea for up to 48 hours should be considered as one missed pill; vomiting and diarrhea for more than 48 hours should be treated as two or more missed pills. For norethindrone-containing progestin-only pills, a pill is considered "missed" if it is more than 3 hours late.

Emergency Contraception

Emergency contraception is used to avoid pregnancy after unprotected sex acts.[14] A formulation of 1500 μg (1.5 mg) levonorgestrel in a single tablet prevents about 85% of expected pregnancies if used within 72 hours after coitus (ideally as soon as possible). Another approved agent for emergency contraception is the selective progesterone receptor modulator ulipristal acetate given as a single 30-mg dose; this agent is more effective than levonorgestrel and is effective for 5 days after intercourse.[A2] Another option is the immediate insertion of a copper intrauterine device (see later), which virtually eliminates the risk of pregnancy. A recent randomized trial found that the levonorgestrel 52-mg IUD was also an effective emergency contraceptive when inserted within 5 days after unprotected intercourse.[A3]

Transdermal and Intravaginal Steroid Contraceptives

Transdermal Patch

In the United States, two transdermal contraceptive patches contain both estrogen and progestin (Xulane and Twirla). The Xulane patch has an area of 20 cm^2 and delivers 150 μg of the progestin norelgestromin, the active metabolite of norgestimate, and 35 μg of ethinyl estradiol daily. Twirla delivers 120 μg of levonorgestrel and 30 μg of ethinyl estradiol daily. Patches may be applied to the buttocks, lower abdomen, upper arm, or upper torso (but not the breasts). The patch should be removed after 7 days, and then a new patch should be applied to a different area of skin. A woman using this method uses three patches sequentially, each for 7 days. After the third patch is removed, the woman waits 7 days before starting her next patch, thus mimicking the 28-day combined oral contraceptive cycle (21 hormone days, followed by 7 hormone-free days, during which withdrawal bleeding occurs). Because the patch does not require daily attention, continuous use is somewhat higher for the patch than for oral contraceptives, but otherwise efficacy, bleeding patterns, side effects, and the contraindications are similar. The effectiveness of the patch may be decreased among women weighing more than 90 kg. Both patches are approved only for people with a BMI <30 kg/m^2.

Intravaginal Ring

Another option for non-oral combined hormonal contraception is the vaginal ring (Nuva-Ring in the United States). This soft, flexible ring measures 58 mm in diameter and is 4 mm thick. The ring is composed of ethinyl vinyl acetate and contains the progestin etonogestrel, a major metabolite of desogestrel, and ethinyl estradiol. The ring is inserted and removed by the user. There is no "wrong" position or placement of the ring inside the vagina. Each ring is left in place for 3 weeks, after which it is removed for 1 week to allow withdrawal bleeding. Each day, 120 μg of etonogestrel and 15 μg of ethinyl estradiol are released from the ring, and bleeding is uncommon with the ring in place. Contraceptive efficacy, side effects, and contraindications are similar to those of combined oral contraceptives. Women may keep the ring in place during intercourse, or it can be safely removed for up to 3 hours and then reinserted. Tampons also may be used concurrently with the ring without affecting its efficacy. The FDA recently approved Annovera, a vaginal ring that may be used for 1 year with 4-week cycles of 3 weeks inserted and 1 week removed; this device releases approximately 13 μg of ethinyl estradiol and 150 μg of the progestin segesterone acetate daily.

Injectable Steroid Contraceptives

Constituents and Use

Although several types of injectable steroid formulations are used for contraception throughout the world, currently the only injectable available in the United States is depot medroxyprogesterone acetate. One formulation contains 150 mg of depot medroxyprogesterone acetate for intramuscular injection, whereas another formulation is a 0.65-mL solution that contains 104 mg of depot medroxyprogesterone acetate for subcutaneous administration. Both must be re-dosed every 3 months (i.e., every 13 weeks). The major contraceptive action of depot medroxyprogesterone acetate is inhibition of ovulation, but it also impedes sperm transport by thickening cervical mucus. Depot medroxyprogesterone acetate has a low failure rate of only 0.1% at 1 year and 0.4% at 2 years.

TABLE 220-3 CONTRAINDICATIONS TO COMBINED HORMONAL AND PROGESTIN-ONLY CONTRACEPTION ACCORDING TO THE U.S. MEDICAL ELIGIBILITY CRITERIA FOR CONTRACEPTIVE USE*

	COMBINED HORMONAL CONTRACEPTION		*PROGESTIN-ONLY CONTRACEPTION*	
CONDITION	**RELATIVE CONTRAINDICATION (CATEGORY 3)**	**ABSOLUTE CONTRAINDICATION (CATEGORY 4)**	**RELATIVE CONTRAINDICATION (CATEGORY 3)**	**ABSOLUTE CONTRAINDICATION (CATEGORY 4)**
Bariatric surgery (malabsorptive type)	Pills only		Pills only	
Gallbladder disease, medically treated	All			
Postpartum <42 days with or without breastfeeding†	All			
Smoker age 35 or older				
<15 cigarettes per day	All			
≥15 cigarettes per day		All		
Deep venous thrombosis (DVT)/pulmonary embolism (PE)‡		All		
Superficial venous thrombosis	All			
Peripartum cardiomyopathy		All		
Migraine headaches with aura		All		
Solid organ transplant (complicated)		All		
Known thrombogenic mutations		All		
Hypertension§		All	DMPA only	
Ischemic heart disease		All	DMPA only	
Stroke		All	DMPA only	
Diabetes complications‖				
Nephropathy, retinopathy, or neuropathy		All	DMPA only	
Vascular disease		All	DMPA only	
Diabetes of >20 years duration		All	DMPA only	
Lupus with positive antiphospholipid antibodies		All	All	
Cirrhosis (severe, decompensated)		All	All	
Liver tumors (hepatocellular adenoma or hepatoma)		All	All	
Breast cancer, current		All		All
Breast cancer, past and no evidence of disease for 5 years	All		All	
Drug interactions				
Certain anticonvulsants (phenytoin, carbamazepine, barbiturates, primidone, topiramate, and oxcarbazepine)¶	All		Pills only	
Lamotrigine**	Pills only			
Rifampin or rifabutin¶	All		Pills only	
Fosamprenavir	All			

*This is a partial list. For the full list of contraindications to each contraceptive method see https://www.cdc.gov/reproductivehealth/contraception/mmwr/mec/summary.html.
†Postpartum <21 days is a Category 4 contraindication for combined hormonal contraception.
‡Deep vein thrombosis/pulmonary embolism may be a Category 3 or 4 contraindication for combined hormonal contraception, depending on risks for recurrent DVT/PE.
§Depending on blood pressure measurement, hypertension may be a Category 3 or 4 contraindication for combined hormonal contraception.
‖Diabetes complications may be a Category 3 or 4 contraindication for combined hormonal contraception, depending on the severity of symptoms.
¶These medications may reduce the efficacy of combined hormonal contraception and progestin-only oral contraceptives.
**Combined oral contraceptives may reduce the efficacy of lamotrigine.
DMPA = depot medroxyprogesterone acetate.

Side Effects

With both formulations, mean endogenous estradiol levels remain above the postmenopausal range (40 to 60 pg/mL) and symptoms of estrogen deficiency do not occur. Bone mineral density may decline during use, but any bone loss is temporary and reverses after stopping depot medroxyprogesterone acetate.

The major side effect of depot medroxyprogesterone acetate is complete disruption of the menstrual cycle. Because this formulation contains only a progestin, endometrial integrity is not maintained, and usually light uterine bleeding occurs at irregular and unpredictable intervals. As duration of therapy increases, the incidence of frequent bleeding steadily declines and the incidence of amenorrhea steadily increases; after 2 years of use, about 70% of users are amenorrheic. After discontinuing this agent, regular ovulation cycles may not resume for as long as 12 months and may result in delay of return to fertility. Because the major reason for discontinuation of all progestin-injectable contraceptives is menstrual irregularity, several combined progestin-estrogen injectables that are given once monthly and produce regular withdrawal bleeding have been developed, but these are not available in the United States.

Most depot medroxyprogesterone acetate users gain between 1.5 and 4 kg in their first year of use and continue to gain weight thereafter. Because depot medroxyprogesterone acetate preparations contain no estrogen, their use does not cause hypertension or thromboembolism. Depot medroxyprogesterone acetate is associated with a reduction in seizures among women with epilepsy, as well as a reduction in painful crises among women with sickle cell disease.

Subdermal Implants

Constituents and Use

The only subdermal implant currently available in the United States is Nexplanon, which is a single 4-cm by 2-mm ethylene vinyl acetate rod containing 68 μg of etonogestrel, the active metabolite of desogestrel.[15] Although it has been approved for 3 years of use, evidence indicates it provides effective contraception for 5 years. The rod, which is packaged in a disposable metal

trocar inserter, does not require a skin incision for insertion but does need an incision for removal. Ovulation is inhibited by the circulating etonogestrel levels, and no pregnancies were reported in three large clinical trials. As with other progestin-only implants, irregular bleeding is the most common clinical complaint. Because efficacy is not user-dependent, the typical-use and perfect-use failure rates are identical and very low, thereby making this method essentially as effective as IUDs and sterilization. Another subdermal implant, Jadelle, consists of two 4.3-cm rods, each of which contains 75 mg of levonorgestrel and is approved for 5 years of contraception; it is not yet available in the United States.

INTRAUTERINE DEVICES

The two intrauterine contraception options that are available in the United States are the copper-containing IUD and the levonorgestrel intrauterine system. Both methods are exceedingly effective, with perfect-use and typical-use failure rates of less than 1%.

The copper T380A IUD, which is approved for use in the United States for up to 10 years, maintains its high levels of effectiveness for at least 12 years. The 52-mg levonorgestrel intrauterine system, which is approved for 5 or 6 years of use, maintains its efficacy for at least 7 years. This latter device releases a dose of approximately 20 μg of levonorgestrel into the endometrial cavity each day, thereby causing atrophy of the endometrial lining and markedly reducing the amount of uterine bleeding. Two newer levonorgestrel-containing IUDs are smaller and designed for use by nulliparous women; a 19.5-mg device is approved for 5 years of use, and a 13.5-mg device is approved for 3 years of use.

The main mechanism of action for the copper IUD is spermicidal. This effect is caused by a local leukocytic response produced by the copper as well as the plastic IUD. The levonorgestrel-releasing IUD acts mainly by preventing transport of spermatozoa through the cervical mucus, thereby preventing fertilization of the ovum. In addition, some women do not ovulate because of the systemic absorption of levonorgestrel. After removal of each type of IUD, the inflammatory reaction rapidly disappears, and resumption of fertility is prompt.

The main difference between the two IUDs is the menstrual bleeding pattern. With the copper IUD, women generally continue to have a regular menstrual period, which may be associated with more pain and heavier bleeding. With the levonorgestrel intrauterine system, irregular bleeding is common in the first 4 to 6 months of use, but then, most women develop amenorrhea, particularly with the devices containing 52 mg of levonorgestrel.

Both IUDs can be easily inserted by any clinician who has been trained. No special tests are needed routinely before insertion, and if it is reasonably certain that the woman is not pregnant, the IUD may be inserted on the same day a patient requests it. An IUD may be safely inserted immediately after a delivery or abortion, although the expulsion rate may be slightly higher.[16]

Almost all patients, including nulliparous and young women, are considered good candidates for the IUD. However, IUDs are contraindicated in women with active pelvic inflammatory disease, purulent cervicitis, unexplained uterine bleeding, or liver disease, as well as in women who have anatomic uterine abnormalities. IUDs are also relatively contraindicated in women who have a history of pelvic inflammatory disease, cervical cancer, or uterine cancer, or who cannot access follow-up care. The copper IUD is also relatively contraindicated in women who have a history of menorrhagia or severe dysmenorrhea.

Uterine perforation is a rare complication of IUD insertion, occurring in less than 0.1% of cases. Spontaneous expulsion of the IUD after insertion is also rare and happens in less than 5% of users. If there is clinical suspicion that cervicitis is present, a test for chlamydia and gonorrhea (Chapter 264) should be performed, and the insertion should be delayed until negative results are obtained. Routine antibiotics are not recommended with IUD insertion.

Development of acute salpingitis more than 1 month after insertion of the IUD is due to infection with a sexually transmitted pathogen and is unrelated to the presence of the device. All IUD-related upper genital tract infections occur only during the insertion process.

PERMANENT CONTRACEPTION

Permanent contraception, also known as sterilization (tubal ligation for women and vasectomy for men), is the most common contraceptive method used by couples in the United States. Female sterilization may be performed transabdominally, such as at the time of cesarean delivery; through a minilaparotomy incision immediately postpartum; or laparoscopically. Laparoscopic tubal ligation may be performed as an outpatient procedure. The use of salpingectomy,[A4] which is also safe and effective, is rising due to a theoretical reduction in the risk of ovarian cancer.

Vasectomy is a simple outpatient procedure that can be performed using local anesthesia. Sexual function is not affected by vasectomy. Programs are available to support contraceptive services for low-income women, but it is often more difficult for low-income men to access vasectomy.

MEDICATION (OR MEDICAL) ABORTION

Mifepristone (a selective progesterone receptor modulator) is used worldwide for the medical termination of pregnancy. The FDA-approved label for mifepristone describes a regimen in combination with misoprostol (a synthetic prostaglandin E_1 analogue) as one 200 mg tablet of mifepristone taken orally followed 24 to 48 hours later by four 200-μg tablets of misoprostol (800 μg total) placed buccally (between the gum and the cheek) for termination of early first-trimester pregnancies.[17] Other routes of misoprostol (sublingual and vaginal) also can be used. This therapy is approved for termination of the pregnancy up to 70 days after the last menstrual period; published evidence supports off-label use through the first trimester, and modified regimens can be used throughout gestation.

Treatment with this abortion regimen is highly successful, with approximately 97% efficacy in the early first trimester (defined as pregnancy terminated without intervention other than the medications). Efficacy is slightly higher if used at earlier gestational ages. The main side effects are uterine cramping and bleeding (which are, in fact, the main intended effects of the treatment), as well as less frequently reported instances of nausea, vomiting, and diarrhea. Serious adverse events, which occur in approximately 0.3% of cases, mainly fall into two categories: consequences of excessive bleeding (e.g., blood transfusion and/or surgical completion of the abortion) or infection, which is even rarer. The risk of death among users of this method is 0.00063%, 14 times lower than the risk associated with live birth. This therapy can be provided as a completely outpatient service, and hence is used by many types of providers, including family medicine and internal medicine physicians, midwives, physician assistants, and nurse practitioners. The standards of service provision have evolved with experience to allow more patient-centered treatment, with users deciding where to be when they take the medication and with whom.

In the United States, the FDA originally required that mifepristone be dispensed directly by a health care provider. During the COVID-19 public health emergency, the FDA temporarily suspended the in-person dispensing requirement and allowed providers to mail the medications to patients or to use a mail-order pharmacy. As of this writing, the FDA has made that change permanent. This policy allows the use of telemedicine to provide medication abortion without an in-person visit. Innovative services using fewer pre-abortion tests and mailing drugs directly to the user have been met with high patient acceptability and good safety and efficacy results.

221 MEDICAL ISSUES IN PREGNANCY

CATHERINE Y. SPONG AND DAVID B. NELSON

Of the over 70 million women of reproductive age in the United States, women are increasingly entering pregnancy at a later age. The mean age was 27.1 years in 2020, up from 23 years in 1994. Pregnancy, which has always served as a stress test for a woman's health, is now becoming even more of a challenge as women, especially non-White women (E-Fig. 221-1), experience it with more underlying comorbid medical conditions that can be exacerbated during pregnancy or at the time of labor and delivery.[1,2] The most common complication is bleeding, which accounts for about 75% of cases of severe maternal morbidity in the United States.[3] However, other conditions that are significantly associated with severe maternal morbidity and mortality (E-Fig. 221-2) include hypertension, diabetes, peripartum cardiomyopathy, thromboembolic disease, sepsis (most commonly from pyelonephritis), suicide, acute fatty liver of pregnancy, and thyroid storm.

GENERAL PRINCIPLES

Because of physiologic changes in pregnancy, maternal drug concentrations (and thus embryo-fetal exposure) are altered from the nonpregnant state. Physiologic changes include alterations in circulating binding proteins, volume of distribution, cardiac output, gastrointestinal transit and absorption, hepatic metabolism, and renal clearance (Fig. 221-1 and Table 221-1). Despite these differences, it is not appropriate to withhold an indicated, or necessary, intervention, simply because of pregnancy or lactation. Comprehensive counseling, including the obstetrician as well as medical surgical experts, and shared-decision making are key to understanding not only the theoretical risks but also the benefits, indications, and alternatives.

Women who enter pregnancy with medical conditions have an increased risk of complications, including preterm birth, preeclampsia, fetal growth restriction, stillbirth, and maternal morbidities. As a general rule, if the medical condition is optimized prior to conception (Table 221-2), the risk of complications to the mother and the fetus is decreased.[4] Many medical conditions affect fetal development, so enhancing access to care before conception or after delivery for intervening births must be a priority and become a central focus of health policy and advocacy. For example, hyperglycemia in the first trimester in diabetic women is associated with diabetic embryopathy, manifested by anencephaly, microcephaly, congenital heart disease, renal anomalies, and caudal regression (Fig. 221-2).[5] Because organogenesis occurs within the first 8 weeks of gestation, glycemic control (Chapter 210) should be optimized prior to conception, aiming for a hemoglobin A_{1C} level less than 6.0. Optimal control of other conditions, such as systemic lupus erythematosus (Chapter 245), can improve the outcome of pregnancy if conception occurs while the disease is in remission.

Medications

For most medical conditions, treatment of women who wish to become pregnant or are pregnant does not differ from routine care, except for the avoidance of drugs that are known to be unsafe for the fetus or situations in which drugs of proven safety are substituted for drugs of unknown safety. The care of all women of childbearing age should avoid medications known to be associated with abnormal fetal development (Table 221-3) unless adequate contraceptive methods (Chapter 220) are ensured.

Radiation Exposure

Radiographs can cause an electrochemical reaction that damages tissue (Chapter 18), thereby resulting in pregnancy loss, fetal growth restriction, congenital malformations, microcephaly, or intellectual disability. Importantly, the impact of radiation on the fetus depends on gestational age.[6] Below a threshold dose (0.05 Gy or 5 rad), radiation poses no risk, and the threshold for gross malformations is about 0.2 Gy (20 rads). Imaging should not be withheld if it is needed for diagnosis, but expert consultation should be obtained, and patients must be counseled regarding risks and benefits. Guidelines no longer require verification of pregnancy status for radiographs that do not directly expose the pelvis (Table 221-4).

TABLE 221-1 NORMAL PHYSIOLOGIC CHANGES IN PREGNANCY

CARDIAC
Cardiac output increased 40%
Blood volume increased 30-50%
Heart rate increased 10-20 beats/min
Blood pressure decreased 10-15 mm Hg
ECG changes related to widened thorax, dextrorotation of heart, elevation of diaphragm
PULMONARY
Upper airway hyperemia and glandular hyperactivity leading to increased edema and friability
Nasal congestion, gestational rhinitis, snoring
Difficult airway management and failed intubation
Minute ventilation increased (owing to an increase in tidal volume, *not* respiratory rate, which remains unchanged), which leads to relative respiratory alkalosis (pH 7.4-7.45)
Pa_{O_2} 100-105 mm Hg
Pa_{CO_2} 28-32 mm Hg
RENAL
Increased GFR to 150-180 mL/min/1.73 m^2
Serum creatinine concentration <0.8 mg/dL
Increased renal excretion of bicarbonate, limiting buffering capacity in patients who become acidotic
Decreased oncotic pressure
ALTERED PHARMACOKINETICS
Increased renal and hepatic clearance of drugs
Altered absorption
Altered protein binding
Increased volume of distribution

ECG = electrocardiogram; GFR = glomerular filtration rate.
These physiologic changes generally progress throughout gestation.
From Rosene-Montella K. Common medical problems in pregnancy. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier Saunders; 2020.

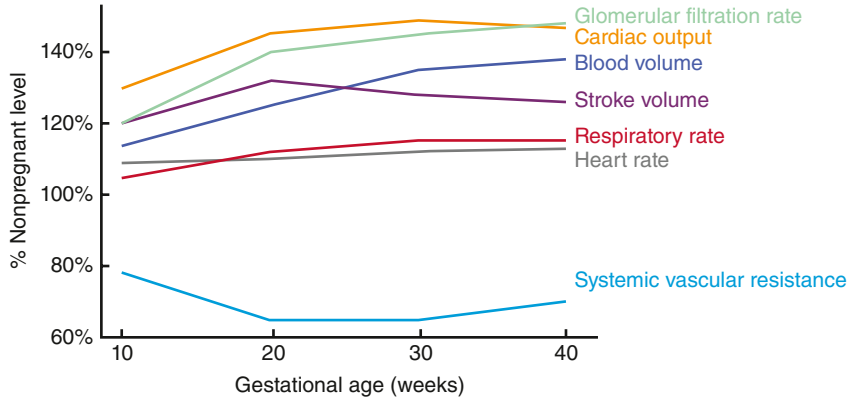

FIGURE 221-1. Physiologic changes associated with pregnancy across gestation compared to the nonpregnant individual.

ABSTRACT

Of the over 70 million women of reproductive age in the United States, women are increasingly entering pregnancy at a later age. The mean age was 27.1 years in 2020, up from 23 years in 1994. Pregnancy, which has always served as a stress test for a woman's health, is now becoming even more of a challenge as women, especially non-White women, experience it with more underlying comorbid medical conditions that can be exacerbated during pregnancy or at the time of labor and delivery. The most common complication is bleeding, which accounts for about 75% of cases of severe maternal morbidity in the United States. However, other conditions that are significantly associated with severe maternal morbidity and mortality include hypertension, diabetes, peripartum cardiomyopathy, thromboembolic disease, sepsis (most commonly from pyelonephritis), suicide, acute fatty liver of pregnancy, and thyroid storm.

TABLE 221-2 PRECONCEPTION INTERVENTIONS FOR PATIENTS WITH MEDICAL ILLNESSES

TYPE 1 AND TYPE 2 DIABETES MELLITUS
Discuss importance of hemoglobin A_{1c} before conception
Evaluate for microvascular complications
Obtain remission proliferative retinopathy
Discuss contraindication of ACE inhibitor in pregnancy
Discontinue thiazolidinediones and statins
Consider change to insulin therapy for type 2 diabetic patients on oral agents unless using metformin for ovulation induction in PCOS
Discuss probable need to reduce insulin dose in first trimester
THYROID DISEASE
Screen for hypothyroidism in women at risk
Normalize TSH and free T_4 before pregnancy
Counsel women taking levothyroxine on need to increase dose soon after conception
Diagnose cause of hyperthyroidism and consider ablative therapy for women with Graves disease requiring high doses of PTU
CHRONIC HYPERTENSION/RENAL DISEASE
Rule out secondary causes of hypertension if appropriate
Evaluate extent of end-organ disease
Quantify GFR and proteinuria
Discuss drugs of choice for hypertension and replace ACE inhibitor
Discuss risk for superimposed preeclampsia and use of low-dose aspirin for women at significant risk for preeclampsia
THROMBOEMBOLIC DISEASE
Consider evaluation for congenital or acquired thrombophilias in women with previous VTE, previous poor obstetric outcome, or family history
Discuss risks of warfarin in pregnancy, need to discontinue warfarin by 4 to 6 weeks' gestation, and conversion to unfractionated or low-molecular-weight heparin
Discuss options to combined oral contraceptives
EPILEPSY
Determine whether patient is a candidate for withdrawal of antiepileptic drugs
Consider monotherapy with most effective agent at lowest dose possible
Prescribe folate at 1 to 4 mg/day
Discuss possible ineffectiveness of low-dose contraceptives with phenobarbital, phenytoin, and carbamazepine
Consider discontinuing valproate
CARDIAC DISEASE
Obtain baseline echocardiography if congenital disease, stenotic lesion, or pulmonary hypertension suspected
Evaluate for coronary artery disease in women with multiple risk factors
ASTHMA
Verify patient's asthma action plan and peak flowmeter use
Discuss relative safety of all asthma medications except leukotriene modifiers
SYSTEMIC LUPUS ERYTHEMATOSUS AND AUTOIMMUNE DISEASE
Evaluate for renal and cardiopulmonary disease and antiphospholipid, anti-Ro, anti-La antibodies
Avoid pregnancy if disease is active
Discuss relative safety of most immunosuppressants

ACE = angiotensin-converting enzyme; GFR = glomerular filtration rate; PCOS = polycystic ovary syndrome; PTU = propylthiouracil; T_4 = thyroxine; TSH = thyroid-stimulating hormone; VTE = venous thromboembolism.

Laboratory Test Results

The physiologic changes in pregnancy alter the normal range of many laboratory values (see Appendix). For example, the increase in plasma volume relative to red blood cell volume results in a physiologic anemia and dilutional decreases in blood levels of albumin, creatinine, and platelets. By comparison, white blood cell levels, particularly neutrophils, and cholesterol, and fibrinogen levels increase across gestation (Table 221-5).[7]

Cardiopulmonary Resuscitation

When clinically indicated, cardiopulmonary resuscitation (CPR; Chapter 50) in a pregnant woman is essential for both maternal and fetal health. Because cardiac arrest is often accompanied by obstetric emergencies, such as amniotic fluid embolism (Chapter 68), understanding the impact of pregnancy on effective resuscitation is critical to optimize outcome. The pregnant woman is at higher risk of hypoxemia, and the gravid uterus causes aortocaval compression when supine. In addition, the gravid uterus elevates the diaphragm, thereby decreasing functional residual capacity by 10 to 25%. Standard high-quality CPR—meaning unchanged hand location, compression depth, and rate—should be initiated immediately along with continuous manual left uterine displacement (E- Fig. 221-3) if the uterus is palpated at or above the umbilicus. Manual left uterine displacement allows for optimal chest compressions while relieving aortocaval compression. If resuscitative efforts are not successful, a perimortem cesarean delivery should begin within 4 minutes so as to minimize fetal neurologic damage and improve maternal resuscitative efforts.

The delivery should be performed at the site of maternal resuscitation, with ongoing resuscitative efforts, rather than transporting the mother to a separate delivery setting.

MEDICAL DISORDERS OF PREGNANCY

HYPERTENSIVE DISORDERS OF PREGNANCY

The hypertensive disorders of pregnancy can be divided into four distinct types: (1) chronic hypertension, (2) preeclampsia and eclampsia, (3) gestational hypertension, and (4) preeclampsia superimposed on chronic hypertension.

CHRONIC PREEXISTING HYPERTENSION

DEFINITION

Chronic hypertension in pregnancy is hypertension that was present before pregnancy, is diagnosed before 20 weeks of gestation, or is diagnosed during pregnancy and does not resolve postpartum. The threshold for defining chronic hypertension in pregnancy is evolving, but recent data suggest 140/90 mm Hg rather than the prior definition of a systolic blood pressure up to 160 mm Hg or a diastolic blood pressure up to 100 mm Hg.

EPIDEMIOLOGY

Chronic hypertension is present in 0.9 to 1.5% of pregnant women when using current definition of 140/90 mm Hg in pregnancy and may result in significant maternal, fetal, and neonatal morbidity and mortality, especially in the context of superimposed preeclampsia. Indeed, superimposed preeclampsia develops in as many as 20 to 50% of pregnant women who have chronic hypertension requiring therapy or systolic blood pressure above 140 mm Hg. The rate of maternal chronic hypertension is increasing, and the largest increase is among non-Hispanic Black women.

PATHOBIOLOGY

Chronic hypertension results in pathologic injury to multiple organ systems (Chapter 64), and adverse outcomes of pregnancy are directly related to the severity, duration, and existing end-organ effects of hypertension before pregnancy and whether superimposed preeclampsia develops. Chronic hypertension, which is a potential precipitant of cardiomyopathy and cerebrovascular events, is associated with a five-fold risk for maternal death, and hypertension is responsible for 6.6% of current pregnancy-related deaths (see Fig. 221-2). Both systolic and diastolic blood pressures normally decline gradually during the first half of pregnancy, so it can be difficult to assess the burden of hypertension in women who enter prenatal care at later gestational ages.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Assessment for possible end-organ effects of underlying chronic hypertension during pregnancy should include measurement of baseline levels of serum creatinine and electrolytes, measurement of urine protein : creatinine ratio, and a 24-hour quantification of proteinuria. Approximately 11% of women with chronic hypertension have proteinuria (>300 mg/day) at baseline. These baseline assessments are useful for comparison if superimposed preeclampsia may later be suspected.

An echocardiogram should assess for left ventricular hypertrophy, which may be present in about 25% of pregnant women who receive antepartum treatment for chronic hypertension and which portends a significantly greater risk for subsequent or superimposed preeclampsia. The diagnosis of superimposed preeclampsia can be challenging and is typically based on the development of significantly worsening hypertension or of new-onset features, such as headache or vision disturbances with scotomata.

TREATMENT

Treatment of chronic hypertension (Chapter 64)[8] may differ somewhat during antepartum care, at delivery, and postpartum. In all these settings, immediate antihypertensive therapy is mandatory for women with hypertension at or above 160/110 mm Hg. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are contraindicated during pregnancy due to their potential teratogenic risks (see Table 221-3), so they should not be used in women of childbearing age (Chapter 220). In general, β-blockers, calcium channel blockers,[A1] and methyldopa (see Tables 64-7 and 64-9) are routinely used during the antepartum period given their safety profiles during pregnancy.

To optimize perinatal outcomes, the goal blood pressure for pregnant women whose chronic hypertension is treated with antihypertensive medications is a blood pressure of 140/90 mm Hg.[A2] Control to a target diastolic blood pressure below 85 mm Hg is no better in terms of fetal outcomes and is only marginally better for reducing the frequency of progression to severe hypertension. Fetal growth may be compromised if blood pressure is treated more aggressively.

Stage-based protocols using checklists, referred to as "safety bundles," have recently been developed through both national and state-based programs for standardization of response.[9] Acute intrapartum antihypertensive therapy emphasizes timely treatment (Table 221-6). Superimposed preeclampsia also requires magnesium sulfate prophylaxis (either a 4- or 6-g intravenous loading dose, followed by continuous infusion of 2 g per hour) and prompt delivery. After delivery, persistent postpartum hypertension is typically managed with β-blockers and calcium channel blockers (see Table 64-7), as used during the antepartum period, for safe lactation and future childbearing considerations.

PREVENTION

In women with well-controlled blood pressure, perinatal outcomes are similar to outcomes in women without chronic hypertension, so a goal for prevention is to control blood pressure before conception. Since women who have chronic hypertension are at increased risk for developing preeclampsia, they should begin taking daily low-dose aspirin (81 mg) between 12 weeks and 28 weeks of gestation (optimally before 16 weeks)[A3] and continue until delivery.[10] Initiating treatment after 28 weeks of gestation is unlikely to be beneficial. Aspirin should not be used in women who have risk factors for gastrointestinal hemorrhage (e.g., bleeding disorders or peptic ulcer).

PROGNOSIS

In patients with chronic hypertension, preeclampsia tends to have an earlier onset and to be more severe, so the prognosis for the woman and her fetus is worse than in either condition alone.

HYPERTENSIVE DISORDERS UNIQUE TO PREGNANCY

The threshold for gestational hypertension and preeclampsia is new-onset blood pressure at or above 140/90 mm Hg. Gestational hypertension is the diagnosis in the absence of proteinuria, whereas preeclampsia is associated with new-onset proteinuria during pregnancy and affects virtually every organ system.

New-onset is arbitrarily defined as at 20 weeks' gestation or later, and proteinuria serves as an objective measure of the endothelial damage caused by preeclampsia. Preeclampsia is further sub-divided into: early-onset (<34 weeks) and late-onset (≥34 weeks).[11,12] Eclampsia is defined by new-onset tonic-clonic, focal, or multifocal seizures in the absence of other causative

TABLE 221-6 URGENT MANAGEMENT OF SEVERE HYPERTENSION (≥160/110 mm Hg) IN PREGNANCY AND THE IMMEDIATE POSTPARTUM PERIOD

DRUG	DOSE
ORAL	
Nifedipine IR	10-20 mg initially and 20 min later, followed by 10-20 mg q 2-6h to a maximum of 180 mg
INTRAVENOUS	
Labetalol (preferred)	10-20 mg then 1-2 mg/min (or 20-80 mg q 10-30 min) to a maximum of 300 mg
or	
Hydralazine	5 mg initially then 0.5-10 mg/hr (or 5-10 mg q 20-40 min) to a maximum of 20 mg

conditions such as epilepsy (Chapter 372), cerebral arterial ischemia and infarction (Chapter 58), intracranial hemorrhage (Chapter 377), or drug use (Chapter 365).[13]

EPIDEMIOLOGY

The most common hypertensive disorder of pregnancy is gestational hypertension, which occurs in 6 to 17% of nulliparous patients and 2 to 4% of parous patients. Preeclampsia is identified in 5 to 8% of all pregnancies, with higher risks in women who are young and nulliparous and in older women who have comorbid conditions such as chronic hypertension. A prior history of preeclampsia raises risks by about eight-fold. Non-Hispanic Black women, obese patients, and women with a family history are also higher risk.[14] The incidence of eclampsia in high-resource settings is now 1 in 2000 to 3000 deliveries.

PATHOBIOLOGY

The mechanisms by which pregnancy provokes hypertension remain unsolved but likely involve genetic, immunologic, and angiogenic responses to hormonal changes and increased blood volume. The first stage, which involves faulty endovascular trophoblastic remodeling, results in a second stage of endothelial dysfunction with overproduction of anti-angiogenic factors—soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng)—that enter the maternal circulation. The phenotypic expression of the preeclampsia syndrome represents a spectrum of disease, with end-organ consequences. Hemoconcentration is a hallmark. Cardiac function becomes compromised owing to an increased afterload, and aggressive fluid support may result in pulmonary edema.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnostic clinical manifestations of the preeclampsia syndrome (Table 221-7) are a blood pressure of 140/90 mm Hg or greater accompanied by proteinuria (≥300 mg/24 hours or a urine protein/creatinine ratio of ≥0.3). Following the initial documentation of proteinuria and the establishment of the diagnosis of preeclampsia, additional quantifications of proteinuria are no longer necessary.

Eclampsia, which is often preceded by neurologic complaints, such as new-onset headache or vision disturbances, should be considered in any pregnant or immediately postpartum patient who presents with convulsions at or near term. The diagnosis depends on the exclusion of other causes of seizures. In most cases, the convulsions are followed by a post-ictal state with an elevated respiratory rate in response to hypercarbia, transient hypoxia, and lactic acidemia. If intracranial bleeding is a concern, immediate brain imaging with CT scanning is indicated. In many cases, eclampsia can be corroborated when an MRI demonstrates signs of reversible encephalopathy, classically in the occipital and parietal cortical regions.

TREATMENT

The medical treatment of gestational hypertension is similar to the management of chronic hypertension. Treatment of preeclampsia aims to prevent eclampsia by using magnesium sulfate (either a 4- or 6-g intravenous load, followed by 2-g per hour infusion) to prevent seizures, immediately treating severe hypertension (160/110 mm Hg or greater; see Table 221-4), and effecting prompt delivery of the fetus. In the absence of contraindications, (e.g., myasthenia gravis; Chapter 390), a patient with convulsions late in pregnancy or early in the postpartum period should empirically be given magnesium sulfate to prevent recurrent seizures even while evaluation is underway. If seizures persist despite ongoing magnesium sulfate prophylaxis, an additional 2-g loading dose should be considered, and agents that significantly depress respiratory function should be avoided. Magnesium sulfate is cleared by the kidney, so women with compromised renal function merit close observation for toxicity, which is manifested by diminished reflexes and respiratory depression. Treatment with calcium gluconate (1 g intravenously over 2 to 5 minutes) and discontinuation of the magnesium sulfate reverses respiratory depression.

Delivery is the only cure for preeclampsia-eclampsia. However, emergent cesarean delivery is not recommended for an eclamptic event in the absence of clinical evidence for placental abruption. Fetal compromise often resolves with maternal supportive care in the minutes following the seizure.

Women should be evaluated for possible fluid overload and pulmonary edema because the majority of women with preeclampsia develop pulmonary edema after birth. Volume expansion with agents, such as albumin, may aggravate pulmonary function, and their use is not routinely recommended. Careful fluid management, diuretics (e.g., furosemide 20 mg intravenously), for pulmonary edema afterload reduction with acute intrapartum antihypertensive agents (e.g., labetalol 10 to 20 mg intravenously, hydralazine 5 to 10 mg intravenously, or immediate-release nifedipine 10 mg orally), airway management, and respiratory support are key.

Preeclampsia and eclampsia also can present during the 6 weeks postpartum. Early diagnosis is critical, and management is the same (e.g., seizure prophylaxis and antihypertensive therapy) as when they present prior to delivery.

TABLE 221-7 CRITERIA FOR PREECLAMPSIA WITH SEVERE FEATURES

FEATURES
SBP ≥160 mm Hg or DBP ≥110 mm Hg on two occasions 4 hours apart (unless antihypertensive therapy initiated)
Thrombocytopenia (<100,000/μL)
Elevated liver function tests (>2 times normal)
Severe persistent right upper quadrant pain
Epigastric pain unresponsive to medications
Renal insufficiency (creatinine >1.1 mg/dL or double baseline)
Pulmonary edema
New-onset headache
Visual disturbances

DBP = diastolic blood pressure; SBP = systolic blood pressure.

PERIPARTUM CARDIOMYOPATHY

DEFINITION

Peripartum cardiomyopathy is defined by left ventricular dysfunction and the development of cardiac failure without another known cause in the final month of pregnancy or up to 5 months postpartum (Chapter 47). It is one of the reasons why cardiovascular-related conditions are now responsible for more than 33% of pregnancy-related deaths in the United States (see E-Fig. 221-2).

EPIDEMIOLOGY

The worldwide incidence of peripartum cardiomyopathy is approximately 1 per 1000 pregnancies but varies by geographic area and ethnicity. In Africa, for example, peripartum cardiomyopathy develops in as many as 1 per 100 pregnancies. In the United States, non-Hispanic Black women have a 5- to 15-fold increased risk compared with other ethnic groups.[15] The overall incidence of peripartum cardiomyopathy in the United States has increased from 1 in 4350 births in the early 1990s to 1 in 2230 births, perhaps in part owing to heightened awareness and improved access to echocardiography, but also likely owing to the obesity epidemic, increasing maternal age, fertility-assisted treatments, and multifetal pregnancies.

PATHOBIOLOGY

Physiologic cardiovascular adaptations to pregnancy include increased blood volume, stroke volume, heart rate, and cardiac output. The current theory is that peripartum cardiomyopathy affects genetically susceptible women who have one of several gene mutations, including *TTNC1*, *TTN*, and *STAT3*. In these susceptible patients, the pregnant state results in substantial secretion of prolactin by the maternal pituitary and high levels of antiangiogenic molecules by the placenta. The 16-kDa prolactin fragment (vasoinhibin) causes myocardial damage, which is compounded by secretion of high levels of the vascular endothelial growth factor inhibitory molecules, such as soluble fms-like tyrosine kinase (sFlt-1).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with peripartum cardiomyopathy typically present with symptoms of heart failure (Chapter 45) in late pregnancy or within 5 months postpartum. An echocardiogram (Chapter 43) should be obtained to exclude valvular heart disease (Chapter 60), pericardial disease (Chapter 62), or segmental wall motion abnormalities that might suggest ischemic heart disease or a coronary artery dissection (Chapter 58). Peripartum cardiomyopathy is ultimately a diagnosis of exclusion after careful assessment of cardiac function by physical examination, laboratory testing, and echocardiography (Fig. 221-3). Transthoracic echocardiography is considered diagnostic when it demonstrates diffuse systolic dysfunction with a left ventricular ejection fraction less than 45%, motion-mode fractional shortening less than 30%, or a left ventricular end-diastolic dimension greater than 2.7 cm/m^2 in the absence of other causes of heart failure, such as hypertensive cardiomyopathy, superimposed preeclampsia, sepsis, or the use of tocolytic β-mimetics agents (e.g., terbutaline).[16]

TREATMENT

The diagnosis of peripartum cardiomyopathy is most frequently made postpartum. For women who are diagnosed before delivery, however, prompt delivery is typically recommended after maternal stabilization. Diuretics, fluid restriction, supplemental oxygen, and management with antihypertensive therapy are the mainstays of immediate care consistent with standard heart failure management (Chapter 46 and 47). Calcium channel and β-blocking agents (see Table 221-4) are commonly used for acute blood pressure control before delivery. After delivery, treatment emphasizes ACE inhibitors and angiotensin-receptor blocking agents to decrease afterload (Chapter 46). To inhibit prolactin, women should not breast-feed. Bromocriptine (1.25 mg to 2.5 mg once daily) may be added if traditional measures are not successful, but use is controversial. Because of the increased risk of thromboembolism, prophylactic anticoagulation with low-molecular-weight heparin (see Table 70-3) is typically instituted. For severe, unremitting heart failure, ventricular-assist devices and extracorporeal membrane oxygenation have been used. Reliable contraception is critical to allow for potential recovery and assessment before future pregnancy is attempted.

PREVENTION

No specific strategies prevent peripartum cardiomyopathy, but control of blood pressure and underlying cardiovascular disease should be optimized before pregnancy. Vigilance may allow for earlier diagnosis of women who have symptoms of heart failure near term and after delivery, thereby allowing earlier treatment before severe clinical deterioration.

PROGNOSIS

Serial echocardiography is recommended to evaluate left ventricular function at 1- to 3-month intervals, and the long-term trajectory of cardiac function is typically clear by 6 months postpartum. In the United States, approximately two-thirds of patients recover ventricular function, but about one-third have a left ventricular ejection fraction persistently below 45%. The risk of recurrence among women who recover left ventricular function during or after subsequent pregnancy is approximately 20%. Women who do not recover should avoid future pregnancies.

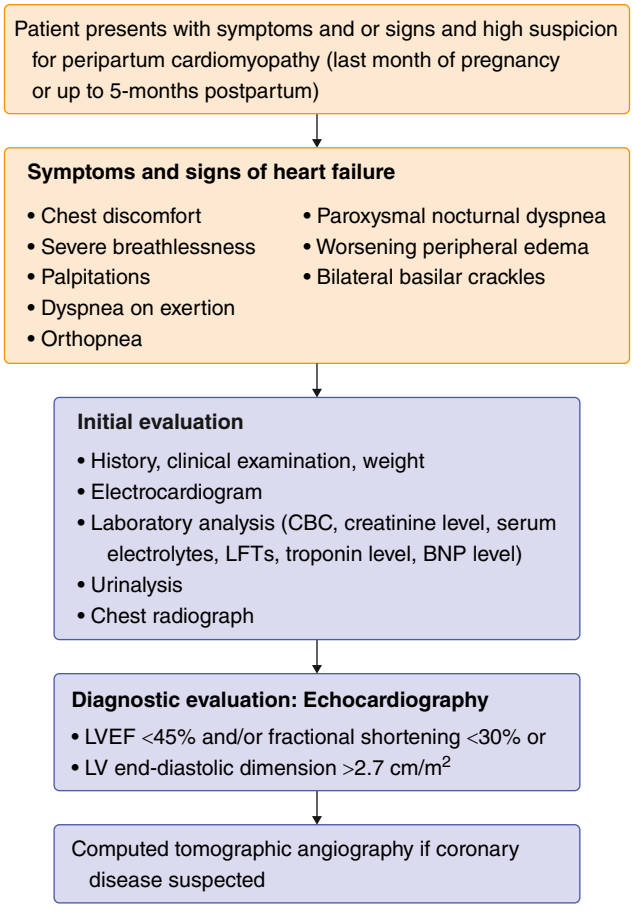

FIGURE 221-3. Evaluation of a patient with suspected peripartum cardiomyopathy. BNP = brain natriuretic peptide; CBC = complete blood count; LFTs = liver function testing; LV = left ventricular; LVEF = left ventricular ejection fraction. (Adapted from Cunningham FG, Byrne JJ, Nelson DB. Peripartum cardiomyopathy. *Obstet Gynecol*. 2019;133:167-179.)

VENOUS THROMBOEMBOLISM

EPIDEMIOLOGY

Pregnancy increases the risk of blood clots, with a sixfold higher incidence of venous thromboembolism (VTE) compared with age-matched, nonpregnant women. The risk increases across gestation, peaking in the peripartum and early postpartum period and continuing through 12 weeks postpartum.

VTE complicates 0.5 to 2 per 1000 pregnancies and represents 9% of maternal deaths (see E-Fig. 221-2). In fact, postpartum VTE is more common than antepartum (0.61 vs. 0.13 per 1000 pregnancies). Pulmonary emboli account for 20% of VTE events.

PATHOBIOLOGY

Increases in estrogen and progesterone during pregnancy result in a hypercoagulable state. Factors I, VII, VIII, and X, as well as von Willebrand factor and plasminogen activator inhibitors (PAI-1 and PAI-2), increase, whereas free protein S decreases. Since these changed levels do not reflect the nonpregnant state, thrombophilias (Chapter 67) are difficult to diagnose during pregnancy, except with DNA testing. The increase in progesterone also results in venodilation, which is further complicated by aortocaval compression of the gravid uterus, thereby increasing venous stasis and the risk that a clot will form.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Deep vein thrombosis (Chapter 68) can be difficult to distinguish from physiologic changes in pregnancy, during which leg swelling, peripheral edema, pain, and dyspnea are common. Over 90% of pregnancy-related deep vein thromboses are in the left lower extremity, in part due to compression of the left iliac vein by the right iliac artery, and classic features include pain and edema. The clinical findings of pulmonary embolism include dyspnea, chest pain, cough, tachycardia, tachypnea, apprehension, and hemoptysis. Importantly 30 to 60% of pregnant women with confirmed lower extremity acute deep vein thrombosis also have an asymptomatic pulmonary embolism.

Although negative D-dimer testing can exclude deep venous thrombosis in the nonpregnant state, it is not clinically useful during pregnancy because it is elevated even in normal pregnancy. In addition, other obstetric conditions, such as preeclampsia, are also associated with further increases in D-dimer levels. The diagnosis of deep vein thrombosis often can be established when compression ultrasonography of the proximal veins (see Fig. 68-3 in Chapter 68)

shows noncompressibility and the echoarchitecture of a thrombosed vein. However, a normal study does not exclude a pulmonary embolism, because the thrombosis may have embolized or arisen from the iliac or deep pelvic veins.[17] Magnetic resonance imaging and/or venography are useful to diagnose iliofemoral or pelvic vein thrombosis.

The diagnosis of pulmonary embolism requires exposure to ionizing radiation, but this risk is mitigated by the greater risk of missing a potentially fatal diagnosis. As in the nonpregnant state, computed tomographic pulmonary angiography is the first-line test for diagnosis (Fig. 221-4).

TREATMENT

During pregnancy, therapeutic anticoagulation with low-molecular-weight heparin (Table 221-8) is the best first-line therapy owing to better bioavailability, a reduced risk of thrombocytopenia and osteoporosis, less frequent dosing, and longer plasma half-life.[A4,18] Unfractionated heparin is an alternative if cost or availability is an issue. Warfarin should be avoided because of its known teratogenicity, especially during the first trimester. Pregnant patients with mechanical prosthetic heart valves are one of the few exceptions in which warfarin can be considered in the second and third trimester. If used in this rare circumstance, women should be converted to unfractionated heparin in the last month of pregnancy or when delivery is imminent (Table 221-8). Direct-acting oral anticoagulants against factor Xa or thrombin are not recommended because of the absence of safety data. For women who are taking low-molecular-weight heparin, anticoagulation should be changed to unfractionated heparin at approximately 36 weeks to prepare for delivery. Pneumatic compression devices are recommended for women who were anticoagulated. If labor occurs while on heparin, aPTT levels can be monitored. Reversal with protamine sulfate is rarely needed and is not indicated for prophylactic heparin.

If a pulmonary embolus occurs at time of delivery, especially a cesarean delivery, a vena caval filter should be considered. Postpartum, anticoagulation includes heparin with the initiation of oral warfarin (titrated to an international normalized ratio [INR] of 2 to 3; see Table 70-4), which is proven safe for lactation; therapeutic heparin anticoagulation is continued for 5 days until the INR is therapeutic for 2 days to avoid paradoxical thrombosis and skin necrosis from the early anti-protein C effect of warfarin. A direct-acting oral anticoagulant (Table 70-6) is an option only if the mother is not going to breast-feed.

PREVENTION

Primary prevention includes avoiding prolonged inactivity or bedrest, or using pneumatic compression devices if unavoidable. The risk of VTE is much higher after cesarean birth as compared with vaginal delivery, so pneumatic compression devices should be used. If additional risk factors, such as previous VTE, are present, both pneumatic compression devices and anticoagulation are recommended. Prophylactic, low-dose antenatal anticoagulation during and after hospitalization for both vaginal and cesarean delivery is controversial. For women who experience a pregnancy-related VTE, evaluation for a possible hypercoagulable state should be undertaken (Chapter 67) after delivery when physiologic alterations have returned to pre-pregnancy state.

PROGNOSIS

With anticoagulation, the prognosis is favorable. For subsequent pregnancies, low-molecular-weight heparin prophylaxis is generally recommended during pregnancy and for the 6 weeks after birth. Importantly, VTE may recur despite antithrombotic prophylaxis, so vigilance is paramount.

MENTAL HEALTH

Perinatal depression includes major and minor depressive episodes (Chapter 362) that occur during pregnancy or in the first 12 months after delivery.[19]

EPIDEMIOLOGY AND PATHOBIOLOGY

Although the incidence of depression varies depending on the definition and population studied, approximately 10% of women have antenatal depression, and another 10 to 20% of women develop postpartum depression. An additional 10 to 20% of women develop "postpartum blues," without meeting the criteria for depression. Maternal self-harm is a significant contributor to pregnancy-related deaths after birth,[20] and mental disorders are now tied with cardiovascular disorders for the number one cause of pregnancy-related death in some states.[21]

Major depression is multifactorial and prompted by genetic factors as well as by environmental factors, such as life events and stressors. Pregnancy itself is a life stressor that can precipitate or exacerbate depressive symptoms, but pregnancy-induced alterations in progesterone and estrogen have also been implicated. Factors associated with perinatal depression include young maternal age, prior history of depression, smoking, and serious adverse perinatal events, including injury or death to the newborn.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Peripartum depression often goes unrecognized because of changes in sleep, appetite, and libido that are inappropriately attributed to normal pregnancy and postpartum changes. Although standard depression screening tools can be used, a validated, targeted tool such as the Edinburgh Postnatal Depression Scale https://www.cope.org.au/health-professionals/health-professionals-3/calculating-score-epds/ is ideal because it consists of just 10 self-reported questions and takes less than 5 minutes to complete. This instrument also includes anxiety symptoms, which are a prominent feature of perinatal mood disorders, but excludes constitutional symptoms of depression, such as changes in sleeping patterns, which can be common in all women during pregnancy and the postpartum period.

Tinzaparin	3500-4500 U/day	3500-4500 U q12h	88 U/kg/day	88 U/kg/day	88 U/kg q12h or 175 IU/kg q24h with anti-Xa monitoring
Heparin	Alternative if LMWH unaffordable: 7500 U bid first 20 wk; 10,000 U bid wk 20-37		Alternative if LMWH unaffordable: 10,000 U bid to achieve anti-Xa level of 0.1-0.3 U/mL		Adjusted to mid-interval anti-Xa of 0.35-0.67 with q12h SQ injections

bid = twice daily; LMWH = low-molecular-weight heparin; SQ = subcutaneously.
Modified from Bourjeily G, Rosene-Montella K, eds. Venous thromboembolism in pregnancy. In: *Pulmonary Problems in Pregnancy, Respiratory Medicine*. New York: Humana Press; 2009.

TREATMENT AND PREVENTION

Although screening and diagnosis alone can have clinical benefits, initiation of treatment or referral to a mental health clinician offers maximum benefit. Current guidelines encourage access to psychological services through primary care clinicians or clinicians embedded within prenatal and postnatal practices,[22] because of the limited availability of other mental health resources. As with depression in general (Chapter 362), cognitive-behavioral therapy is recommended for mild symptoms. Antidepressants (see Table 362-5), predominantly selective serotonin reuptake inhibitors, are recommended in concert with psychotherapy for moderate to severe illness that is unresponsive to cognitive-behavioral therapy. For all agents, shared decision-making regarding risks and benefits is recommended. For severe, otherwise refractory postpartum depression, brexanolone is available as a continuous intravenous infusion over a period of 60 hours at a certified health care facility under the close supervision of a health care provider.[23] Regardless of the medication selected, the risk-benefit balance must be considered with the patient's input in a shared-decision making model, especially during the pregnancy.

Prevention focuses on identifying perinatal mood disorders early so that intervention can avoid more serious progressive disease. In addition, ensuring adequate access to mental health services beyond the postpartum period is important to reduce the risk of future depressive events.

PROGNOSIS

Perinatal depression is frequently recurrent, and up to 70% of women have a subsequent episode with a future pregnancy. In addition, women with history of perinatal mood disorders, including "postpartum blues," have a substantially increased risk for later-life depressive episodes.

ENDOCRINE DISORDERS

DIABETES MELLITUS

DEFINITION

Diabetes mellitus (Chapter 210), which is the most common medical complication in pregnancy, affects women who are diagnosed before pregnancy (pre-gestational diabetics) and women who are diagnosed during pregnancy (gestational diabetes). Gestational diabetes is defined by exceeding thresholds on a glucose challenge test during pregnancy.

EPIDEMIOLOGY AND PATHOBIOLOGY

About 1 to 2% of US pregnancies are complicated by diabetes. In the United States, this rate has increased over the past 20 years, paralleling the trend in obesity.

Gestational diabetes is a form of type 2 diabetes (Chapter 210) that is precipitated by the physiologic changes in glucose metabolism, such as insulin resistance. For the same reasons, pregnancy can exacerbate pre-existing (pre-gestational) type 1 or type 2 diabetes. Women who develop gestational diabetes are at increased risk of developing type 2 diabetes after pregnancy.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis of pregestational diabetes is based on a fasting blood glucose above 125 mg/dL, a 2-hour or random blood glucose level of 200 mg/dL or more, or a hemoglobin A_{1c} level of 6.5% or higher.

Gestational diabetes is almost always asymptomatic and is diagnosed by a screening test that is typically performed between 24 and 28 weeks of pregnancy, unless earlier screening is recommended by risk factors, such as previous gestational diabetes, because treatment significantly improves fetal outcomes. The diagnosis of gestational diabetes based on the results of a blood glucose screen after a single oral challenge of 75 g of glucose is as good as a 2-step diagnosis based on a 50-g glucose challenge test followed by a 3-hour confirmatory 100-g oral glucose tolerance test in terms of predicting perinatal and maternal complications.[A5]

TREATMENT AND PREVENTION

In women who have pregestational diabetes, control should be optimized prior to conception. Insulin, with either continuation or adjustment of the current regimen, is the treatment of choice.[24] For type 2 diabetic women who have not been taking insulin, the initiation of insulin is preferable to oral hypoglycemic agents.[A6] Newer oral agents have not been extensively studied in pregnancy and are not recommended given lack of safety data.

The management of gestational diabetes is based on the fasting glucose level. The initial treatment is diet[A7] and exercise,[A8] with a carbohydrate-restricted diet. In additional to regular meals, three daily snacks are recommended. If euglycemia cannot be obtained with diet and exercise, insulin should be initiated (Chapter 210), typically with 0.7 to 1.0 units/kg/day in divided doses, aiming for a fasting glucose level of 99 mg/dL or a 2-hour postprandial level of 162 mg/dL.[A9] Two thirds of the total dose is given in the morning before breakfast, of which one third should be short-acting regular insulin, and two thirds an intermediate-acting NPH insulin. The remaining one-third of the total dose is given in the evening before dinner, with half as regular and half as NPH. The dose of insulin should then be titrated based on a capillary blood glucose level measured four times daily: fasting and 2 hours after each meal, with targets of less than 95 mg/dL fasting and less than 120 mg/dL at 2 hours after the meal. If the glucose level is measured at 1 hour after each meal, the target is less than 140 mg/dL.

Because of the impact of hyperglycemia on fetal growth and development, strict control is preferred. Insulin requirements may increase with advancing gestation as the fetus and placenta grow, so weekly values must be reviewed and insulin adjusted accordingly.

PROGNOSIS

Pregestational diabetes is associated with adverse outcomes for both the fetus and mother. Fetal complications include spontaneous abortion, preterm birth, congenital malformations, fetal growth restriction (commonly in women who have vascular disease) or fetal macrosomia, stillbirth, and polyhydramnios. The rate of congenital malformations, which is at least doubled, is related to glycemic control during organogenesis (Fig. 221-2). Maternal complications include an increased risk of preeclampsia. Diabetic ketoacidosis (Chapter 210) develops in 1% of pregnancies, commonly at blood glucose levels that are lower than in nonpregnant women.

The primary impact of gestational diabetes is macrosomia, which can be associated with birth trauma, but treatment of even mild gestational diabetes is associated with lower risk of fetal macrosomia. Gestational diabetes is a risk factor for developing diabetes after pregnancy.

THYROID

Fetal thyroid function is directly related to maternal thyroid function and medication use. Defining both hyperthyroidism and hypothyroidism (Chapter 207) follows similar principles during pregnancy as for the nonpregnant patient, with the caveat of the need to consider gestational age-dependent thresholds for levels of thyroid-stimulating hormone (TSH) and free thyroxine.

EPIDEMIOLOGY AND PATHOBIOLOGY

Depending upon the population surveyed, overt hypothyroidism complicates approximately 10 per 1000 pregnancies, whereas subclinical hypothyroidism

occurs with rates approaching 2 to 3%. By comparison, hyperthyroidism is substantially less commonly encountered.

In pregnancy, maternal serum concentrations of thyroid binding globulin are increased, thereby raising the total thyroxine level. Serum free thyroxine (free t4) levels rise only slightly, peak along with human chorionic gonadotropin (hCG) levels, and then return to normal. Although TSH does not cross the placenta, maternal thyroxine does and is important for fetal brain development, especially during the first trimester.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

During pregnancy, the vast majority of cases of hyperthyroidism are caused by Graves disease, whereas Hashimoto thyroiditis is the most common cause of hypothyroidism (Chapter 207). However, the diagnosis of thyroid disease during pregnancy can be challenging, especially because pregnancy itself can mimic the oftentimes nonspecific symptoms of both hypothyroidism and hyperthyroidism. A detailed history and physical examination must be accompanied by measuring serum levels of TSH and free thyroxine and interpreting those results in the context of gestational-age-specific laboratory thresholds. In general, the recommended TSH level is about 0.6 to 3.4 mIU/L in the first trimester, 0.37 to 3.6 mIU/L in the second trimester, and 0.38 to 4.0 mIU/L in the third trimester. The excess thyroxine associated with elevations of hCG early in pregnancy may be confused with overt hyperthyroidism. Life-threatening thyroid storm can be confused with other pregnancy-related complications, such as preeclampsia. Post-ablative hypothyroidism for treatment of Graves disease is also frequently encountered in the pregnant population.

TREATMENT

To treat hyperthyroidism, propylthiouracil (PTU; 50 to 100 mg three times daily) is typically chosen in the first trimester with transition to methimazole (10 to 20 mg daily) for the second trimester and beyond; the lowest possible dose should be used to maintain thyroid indices in the upper-normal range for a given trimester. Symptoms can also be controlled with beta-blocking agents (e.g., propranolol 30 mg per day; see Chapter 207). Serial assessment of thyroid analytes, free thyroxine, free triiodothyronine, and TSH is typically conducted at 4 to 6 weeks to assess whether the dose should be adjusted. Thyroid ablation with therapeutic radioactive iodine is contraindicated during pregnancy.

Treatment of hypothyroidism with thyroxine supplementation (Chapter 207) follows similar principles, albeit with less risk associated with medication crossing the placenta. In approximately one-third of cases, pregnancy is associated with increased dosing requirements due to normal physiologic changes. For women who are already receiving thyroxine supplementation, the dose should be increased by 25% at the initiation of prenatal care because of diminished natural thyroid reserve.

PROGNOSIS

For both overt hyperthyroidism and hypothyroidism, pregnancy outcomes largely depend upon whether metabolic control was achieved. In most cases, the infant is born euthyroid. For subclinical thyroid disease during pregnancy with an elevated TSH level or a low free T_4 level, thyroid hormone–replacement therapy has no impact on the outcomes of pregnancy or the fetus, including no impact on the cognitive function of the children or on other indexes of neurodevelopment through 5 years of age. In the absence of symptoms or risk factors, routine screening for subclinical hypothyroidism is not recommended.[A10]

GASTROINTESTINAL AND LIVER DISEASE IN PREGNANCY

During pregnancy, the enlarging uterus displaces abdominal contents and alters the typical findings on physical examination for common disorders, such as appendicitis (Chapter 128). Gastroesophageal reflux (Chapter 124), manifest clinically as heartburn, is often associated with pregnancy due to the decreased tone of the lower esophageal sphincter. Measures of laboratory analytes associated with hepatic function are altered during pregnancy, and the reference ranges for nonpregnant values may not be applicable to the obstetric patient (see Table 221-8). For example, the normal total alkaline phosphatase level nearly doubles owing to placental production, the serum albumin concentration declines because of the pregnancy-associated increases in plasma volume, and pro-coagulant production is markedly increased. These laboratory changes are often dependent upon gestational age.[25]

Pregnancy can be associated with a variety of liver diseases (Table 221-9). Since the clinical presentations of these conditions can overlap, it is important to distinguish among a chronic liver disease that predates pregnancy, an acute process that occurs coincidentally during pregnancy, and an obstetric condition that is unique to pregnancy.

TABLE 221-9 LIVER DISEASES IN PREGNANCY

UNIQUE TO PREGNANCY
Acute fatty liver of pregnancy
HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets)
Hyperemesis gravidarum
Intrahepatic cholestasis of pregnancy
Preeclampsia and eclampsia
INCREASED INCIDENCE DURING PREGNANCY
Budd-Chiari syndrome
Drug-induced hepatotoxicity
Gallstones
Sepsis
UNDERLYING CONDITION THAT MAY BE REVEALED
Autoimmune hepatitis
Cirrhosis
Hepatitis B and C
Primary biliary cirrhosis
Primary sclerosing cholangitis
Wilson disease

Modified from Mufti AR, Reau N. Liver disease in pregnancy. *Clin Liver Dis.* 2012;16:247-269.

HEPATITIS

Viral hepatitis during pregnancy, whether acute (Chapter 134) or chronic (Chapter 135), can affect the well-being of both the mother and infant. Cases are overwhelmingly due to the classic hepatitis viruses (A to E), most often by hepatitis B or hepatitis C, but rare cases can be caused in pregnant women by cytomegalovirus (Chapter 347), herpesvirus (Chapter 345), and Epstein-Barr virus (Chapter 348).[26] Depending on the timing and chronicity of infection, the risk of vertical transmission to the fetus or infant is an important consideration in management before, during, and after delivery.

EPIDEMIOLOGY

The incidence of viral hepatitis during pregnancy is similar to the risk in the nonpregnant population with similar demographic characteristics. Hepatitis B virus vertical transmission is responsible for approximately 50% of chronic infections worldwide, so prevention of mother-to-child transmission is an important component of maternal care. The risk of developing chronic hepatitis B infection is as high as 90% in infants who are exposed at birth without vaccination, but maternal screening programs and universal vaccination of infants have significantly reduced transmission rates. For hepatitis C virus, an increasing number of infections are occurring among women of childbearing age, so perinatal transmission is increasing. For example, 0.24% of live births in the United States in 2020 were delivered by women with hepatitis C infection reported. The recent availability of effective antiviral medications to treat hepatitis C (Chapter 135) has contributed to recommendations that all pregnant women be screened for hepatitis C.

PATHOBIOLOGY

Both hepatitis B virus and hepatitis C virus are transmitted by parenteral and sexual contact. Acute hepatitis B virus infection early in the pregnancy has been associated with a 10% perinatal transmission rate, and transmission rates significantly increase if acute infection occurs at or near the time of delivery. Approximately 10 to 20% of women who are seropositive for HBsAg alone transmit the virus to their neonates in the absence of neonatal immunoprophylaxis. In women who are seropositive for both HBsAg and HBeAg, the frequency of vertical transmission increases to approximately 90% without neonatal prophylaxis. Importantly, hepatitis B infection acquired perinatally carries an 85 to 95% risk of persistence and chronic infection, with a 25 to 30% life-time risk of serious liver disease. When acute hepatitis B infection occurs in the first trimester, up to 10% of neonates will be seropositive for HBsAg, but 80 to 90% of offspring will be infected if the mother was acutely infected in the third trimester. For hepatitis C, approximately 5 to 6% of infants born to women with infection will become infected.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pregnant women may or may not be symptomatic, and jaundice can have multiple causes. The diagnosis depends on serologic testing (Chapter 134).

For screening, HBsAg is measured at the beginning of prenatal care, with additional testing as necessary to confirm the disease and its severity.[27] The diagnosis of hepatitis C is confirmed by the identification of the antibody to hepatitis C virus. Hepatitis C viral RNA also can be detected by polymerase chain reaction assay of serum soon after infection, as well as in chronic disease.

TREATMENT

Indications for antiviral therapy for hepatitis B in pregnant women are the same as in patients who are not pregnant (Chapters 134 and 135), with tenofovir as the preferred therapy because of its potency, safety profile in pregnancy, and low risk of resistance. At this time, treatment for hepatitis C is not recommended during pregnancy but should be initiated after delivery.

PREVENTION

For purposes of pregnancy, prevention primarily centers on diminishing risk of vertical infection to the fetus and infant. Universal active immunization against hepatitis B virus is recommended for all infants born in the United States (Chapter 15). Infants of women who are HBsAg positive or whose status is unknown at the time of delivery also should receive both hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine, given intramuscularly within 12 hours of birth simultaneously at different sites. The initial vaccination should then be followed by two more injections at 1 and 6 months of life. The combination of passive and active immunization has 85 to 95% efficacy in reducing the frequency of perinatal transmission of hepatitis B virus. Currently, no preventive measures are available to lower the risk of vertical transmission of hepatitis C virus infection. Breast-feeding is not contraindicated in women who are chronically infected with hepatitis B if the infant receives HBIG passive prophylaxis and vaccine active prophylaxis, or in women with hepatitis C virus infection.

PROGNOSIS

Pregnancy per se has not been shown to influence the progression of hepatitis B or hepatitis C. The vertical transmission of infection to the infant, however, carries significant consequences later in the child's life.

GASTROINTESTINAL AND LIVER DISEASES UNIQUE TO PREGNANCY

Hyperemesis Gravidarum

EPIDEMIOLOGY AND PATHOBIOLOGY

Nausea and vomiting are common during pregnancy, with prevalence rates as high as 50 to 80%. When severe and unresponsive to antiemetic therapy, hyperemesis gravidarum is the likely cause. Hyperemesis gravidarum is the most common indication for hospital admission during early pregnancy and is second only to preterm labor as a reason for hospitalization during pregnancy.[28]

Maternal factors associated with hyperemesis gravidarum include migraine headaches, motion sickness, and a personal or family history of the disorder in prior pregnancies. Pregnancy-specific conditions that are associated with hyperemesis gravidarum include multifetal pregnancies and molar gestations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hyperemesis gravidarum is typically defined as persistent vomiting, beginning before 9 weeks of gestation and resulting in weight loss, dehydration, or starvation. For later-onset symptoms, the differential diagnosis includes other common gastrointestinal conditions encountered outside of pregnancy, such as genitourinary infections and metabolic disorders. New-onset nausea and vomiting in the third trimester is associated with acute fatty liver of pregnancy and should not be confused for hyperemesis gravidarum.

TREATMENT

Early outpatient treatment of nausea and vomiting with conservative measures and first-line antiemetic agents, (e.g., pyridoxine 10 mg plus doxylamine 10 mg) is encouraged to prevent progressive symptoms. When hyperemesis gravidarum develops, admission is warranted to provide intravenous crystalloids to correct dehydration as well as parenteral antiemetics (e.g., ondansetron 4 mg every 8 hours) for symptomatic relief. Correction of ketosis and vitamin deficiency should be managed with thiamine (100 mg intravenously) to prevent Wernicke encephalopathy (Chapter 384). Early enteral tube feeding is not helpful.[A11]

PREVENTION AND PROGNOSIS

No preventive measures are known to be effective. Fortunately, hyperemesis gravidarum rarely negatively affects the pregnancy, and it has no significant association with congenital anomalies.

Intrahepatic Cholestasis of Pregnancy

DEFINITION

Intrahepatic cholestasis of pregnancy, which occurs during the second and third trimester and resolves after delivery, is characterized by pruritus, typically in the absence of a rash, and elevated serum levels of bile acids. This condition poses little risk to the mother but substantial risks to the fetus.[29]

EPIDEMIOLOGY AND PATHOBIOLOGY

Intrahepatic cholestasis of pregnancy is the most common pregnancy-specific liver disorder. The incidence ranges from 0.3 to 15% depending upon the population surveyed, with most estimates being approximately 0.5%. Importantly, only approximately 50% of women with clinically suspected intrahepatic cholestasis of pregnancy are confirmed to have the condition.[30] Women with underlying liver conditions, prior intrahepatic cholestasis of pregnancy, multiple gestations, and a familial history are at highest risk.

The cause and course of intrahepatic cholestasis of pregnancy are poorly understood. Once formed, bile acids are exported out of hepatocytes by specific transport proteins, such as the ATP-binding cassette (ABC) transporters, with most transport pumps belonging to the subfamily B (ABC-B). One of the primary bile acid transport proteins is the ABCB-4 pump. The *ABCB4* gene encoding the multidrug resistance 3 (MDR3) protein is primarily involved in a subtype of progressive familial intrahepatic cholestasis. However, this defect likely represents just one example of a number of bile acid transport disruptions that lead to the disorder.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

During pregnancy, pruritus is a common complaint, reported in nearly one-quarter of women. Dermatologic conditions associated with pruritus specific to pregnancy include atopic eruption of pregnancy, pruritic urticarial papules and plaques, and intrahepatic cholestasis of pregnancy. However, the pruritus associated with intrahepatic cholestasis of pregnancy is often generalized, worse at night, and not typically associated with a rash, with the exception of excoriations. If localized, pruritus is typically reported on the palms and soles.

A detailed history and physical examination is indicated. Serum levels of bile acids and aminotransferases should be measured (Table 221-10). The diagnosis of intrahepatic cholestasis of pregnancy is based upon symptoms and a total bile acid level greater than 10 μmol/L in the absence of another explanation. A bile acid level 100 μmol/L or greater is associated with an increased risk of stillbirth.

TREATMENT

The first-line treatment for symptomatic intrahepatic cholestasis of pregnancy is ursodeoxycholic acid (300 mg twice daily), which is effective for relieving pruritic symptoms and improving laboratory values but does not improve fetal outcomes.[A12] Currently, women with severe intrahepatic cholestasis of pregnancy (bile acid levels ≥ 100 μmol/L) are recommended for late preterm delivery (36 to 37 weeks) to avoid the risk of stillbirth, whereas women with bile acid levels below 100 μmol/L are offered delivery at 36 to 39 weeks gestation.

Prevention and Prognosis

To date, no strategies are proven to prevent intrahepatic cholestasis of pregnancy. Following delivery, symptoms typically resolve in several days, and aminotransferase levels gradually decline. Contraception is recommended until aminotransferase levels return to normal. During interval resolution, nonhormonal contraception options are considered. Once recovered, estrogen-containing contraceptives are acceptable although they may precipitate recurrent disease. The future risks of gallstone disease and of recurrence during future pregnancies are increased.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy, which is a rare but potentially fatal condition, is characterized by hepatic failure, typically occurring in the third trimester.

EPIDEMIOLOGY AND PATHOBIOLOGY

The reported incidence varies from 1 in 7000 to 1 in 20,000. Associated risk factors include multiple gestation and fetal fatty acid oxidation disorders.

TABLE 221-10 LABORATORY AND CLINICAL FINDINGS WITH GASTROINTESTINAL COMPLICATIONS OF PREGNANCY

DISORDER	CREATININE	HEMATOCRIT	PLATELETS	FIBRINOGEN	HEMOLYSIS	AST	BILIRUBIN	CLINICAL FINDINGS
Hyperemesis gravidarum	↑	Normal	Normal	Normal	No	Normal-↑↑	Normal -↑↑	Severe nausea and vomiting
Preeclampsia	Normal-↑	↑	Normal-↓↓	Normal	Mild	Normal-↑↑	Normal	Hypertension, headache
Intrahepatic cholestasis	Normal	Normal	Normal	Normal	No	Normal-↑	Normal-↑↑	Pruritus, jaundice
Acute fatty liver of pregnancy	↑-↑↑	↓-↑	↓	↓↓	↑↑-↑↑↑	↑↑	↑↑	Nausea and vomiting, hypertension, abdominal pain, encephalopathy
Hepatitis	Normal	Normal	↓	↓	No	↑↑↑↑	↑↑↑	Nausea and vomiting, jaundice

AST = aspartate aminotransferase.
Adapted from Nelson DB, Byrne JJ, Cunningham FG. Acute fatty liver of pregnancy. *Obstet Gynecol.* 2021;137:535-546.

Despite a well-known association with preeclampsia, the direct cause and effect remains unclear.

Autosomal recessive mutations in genes that encode for enzymes for the fatty acid metabolism pathway cause both the clinical features and histologic microvesicular fatty hepatocyte infiltration seen in Reye syndrome in children and in acute fatty liver in pregnant women. An example of commonly affected enzyme in acute fatty liver of pregnancy is long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD). During normal pregnancy, the fetal-placental unit metabolizes free fatty acids for fetal growth and development. Placental enzymes catabolize triglycerides into free fatty acids, which are then transferred to the fetus. When defects exist in the fatty acid oxidation pathway of the fetal-placental unit, intermediate fatty acid metabolites accumulate and enter the maternal circulation. These intermediate metabolites and associated reactive oxygen species are taken up by the maternal liver where they cause microvesicular fatty infiltration, activate inflammatory processes, and precipitate hepatic cellular necrosis. The mechanism leading to the accumulation of fatty acids and metabolites in the maternal compartment involves two processes. First, the fetal-placental unit shares either a homozygous or compound heterozygous mutation resulting in an enzymatic defect. Second, a heterozygous mother has a decreased ability to accomplish fatty acid oxidation in late pregnancy, thereby leading to an inability to clear the accumulating fatty acid metabolites that are transferred from the deficient fetal-placental unit.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Common symptoms include nausea, vomiting, abdominal pain, often accompanied by hypertension. However, the manifestations of acute fatty liver of pregnancy range from minimal clinical findings and laboratory derangements to overt liver failure (Chapter 140) with hepatic encephalopathy.

The diagnosis of acute fatty liver of pregnancy can be challenging. The most frequent obstetric condition confused with it is the more prevalent hemolysis, elevated liver enzyme, and low platelets (HELLP) syndrome (Chapter 158).[31] Both conditions are associated with significant maternal and perinatal morbidity and mortality, but new-onset nausea and vomiting in the third trimester is often associated with acute fatty liver of pregnancy, which can be confirmed by meeting six of the diagnostic criteria (Table 221-11).

TABLE 221-11 SWANSEA DIAGNOSTIC CRITERIA FOR ACUTE FATTY LIVER OF PREGNANCY

Six or more of the following features in the absence of another explanation:

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin
- Hypoglycemia
- Elevated urate
- Leukocytosis
- Ascites or bright liver on ultrasound scan
- Elevated transaminases
- Elevated ammonia
- Renal impairment
- Coagulopathy
- Microvesicular steatosis on liver biopsy

From Ch'ng CL, Morgan M, Hainsworth I, et al. Prospective study of liver dysfunction in pregnancy in Southwest Wales. *Gut.* 2002;51:876-880.

TREATMENT

The clinical management of the patient with acute fatty liver of pregnancy relies on prompt recognition with in-hospital evaluation and care; supportive measures, such as reversal of coagulopathy; preparation for delivery as soon as feasible; and multidisciplinary care. Hepatic injury will continue until delivery, and maternal recovery may require days to weeks. Close maternal and fetal care should include monitoring, preparation in anticipation of the need for blood products, and a magnesium sulfate infusion if preeclampsia is being considered. Blood pressure should be controlled (see Table 221-5), with a goal of less than 160/110 mm Hg. If the patient is encephalopathic or obtunded, airway protection is critical and may require endotracheal intubation. Up to 15% of women with acute fatty liver of pregnancy will develop pancreatitis.

After delivery, serial measurements of hematologic, hepatic, and renal function should be performed every 6 to 12 hours for the first 1 to 2 days. Blood product replacement is often required because of the risk of postpartum hemorrhage, hemolysis, and diminished pro-coagulant production. Similarly, blood glucose levels should be monitored hourly, and hypoglycemia should be treated with an infusion of 10% glucose.

PROGNOSIS

Clinical recovery should usually be within a week following delivery. Hepatic dysfunction usually begins to improve 1 to 2 days after delivery. Aminotransferase levels decline linearly to levels of 100 units/L or less but may remain mildly elevated for several weeks. Hemostatic dysfunction related to liver synthetic function as well as consumptive coagulopathy improves over 4 to 6 days postpartum. In contrast, renal recovery, as measured by the serum creatinine level, may require 7 to 10 days. Rarely, expected hepatic recovery does not occur, and persistent liver failure may require transplantation.

INFECTIOUS DISEASE

PYELONEPHRITIS

Genitourinary tract infections are the most frequent bacterial infections in pregnancy. Infection that involves the renal calyces, pelvis, and parenchyma is referred to as pyelonephritis (Chapter 263).

EPIDEMIOLOGY AND PATHOBIOLOGY

Pyelonephritis, which is the leading cause of septic shock in pregnancy, is often preceded by asymptomatic bacteriuria, which develops in 2 to 7% of women. If asymptomatic bacteriuria is not treated, up to 25% of pregnant women will progress to symptomatic infection.

Female anatomy predisposes to risk of genitourinary infection, with a shorter urethra, proximity to the vagina and rectum, and common flora at the perineum. Regardless of trimester, the most common organism leading to pyelonephritis is *Escherichia coli* (Chapter 280), but other pathogens include *Klebsiella*, *Enterobacter*, and *Proteus* species (Chapters 281 and 282). Within pregnancy, urinary stasis, vesicoureteral reflux, and pregnancy-related alterations to the T-helper cell (T_H1/T_H2) ratio further enhance susceptibility to infection of the upper genitourinary tract. With urosepsis, endotoxin-induced alveolar damage can lead to respiratory insufficiency that may be further worsened by tocolytic agents, such as β-mimetics.

DIAGNOSIS

The diagnosis of pyelonephritis during pregnancy is suspected with clinical findings of fever, flank pain manifest as costovertebral tenderness on examination, and urinary complaints. Patients present most commonly during the second trimester. The differential diagnosis includes labor, chorioamnionitis, appendicitis, and adnexal torsion. Following a careful history and physical examination, a catheterized urine collection should be obtained to avoid contamination from the lower genital tract. Urinalysis reveals bacteriuria, leukocytes, and nitrites. Urine and blood cultures should be obtained.

TREATMENT

Hospital admission is advised for suspected cases of pyelonephritis during pregnancy. Intravenous fluid support to preserve adequate urinary output is paramount. Empirical antibiotics targeting anticipated pathogens should be initiated promptly (Chapter 266).[32] Typical initial empirical regimens include either ceftriaxone (1 g every 24 hours) or ampicillin (1 g every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours). Intravenous antibiotics should then be tailored to culture results once available. Supportive care includes antipyretics, serial maternal assessment, and fetal monitoring for viable gestations. Notable alterations to maternal blood pressure, pulse, or respiratory function may be early indicators of urosepsis. In general, a mean arterial pressure of at least 65 mm Hg is needed to preserve maternal-fetal perfusion. If necessary despite fluid resuscitation, norepinephrine is the first-line vasopressor recommended during pregnancy (Chapter 94).[33] The clinical course is typically 3 to 4 days of recurrent spiking fevers but with gradual improvement in the temperature curve and peak fevers. For unresponsive infections after 3 to 4 days, genitourinary imaging with either sonography or magnetic resonance imaging is recommended to exclude nephrolithiasis, a perinephric abscess, or an anatomic abnormality that may be causing obstruction.

Following acute resolution of infection, intravenous antibiotics are typically transitioned to a 10- to 14-day course for outpatient management tailored to culture results. Thereafter, oral antibiotic suppression for the remainder of pregnancy is recommended because about one-third of women will have recurrent infection.

PREVENTION AND PROGNOSIS

Pregnant women should be screened for asymptomatic bacteriuria at least once during early pregnancy. Any infection should be treated (see Chapter 263), with a follow-up culture to ensure success. Beyond the immediate infection, neither mother nor fetus have any long-term sequelae treatment.

COVID-19

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 336) and the disease it causes (coronavirus disease 2019; COVID-19) puts pregnant women at increased risk for hospitalization and intensive care unit admission, and it puts their fetus at increased risk of preterm birth.[34,35] Management requires a multidisciplinary team. Delivery may not improve outcomes. Vaccination during pregnancy is highly protective against infection during pregnancy and is strongly recommended.[36]

222 MENOPAUSE

NANETTE SANTORO AND GENEVIEVE NEAL-PERRY

DEFINITION

Menopause is defined as the permanent cessation of menses and is the culmination of a process of reproductive aging that typically occurs in the fifth to sixth decades of life, with a median age of 52.5 years.

EPIDEMIOLOGY

Menopause is a universal phenomenon among women, and its lived experience varies by individual. The advent of menopause and the coincident loss of gonadal steroids significantly affect multiple organ systems in affected women, thereby resulting in an increased risk for osteoporosis (Chapter 225), dementia (Chapter 371), and heart disease (Chapter 40).

Many factors influence the timing of the final menstrual period for any given woman (Table 222-1). Knowing one's mother's age at her final menstrual period is a strong predictor of when a woman is likely to have her own.[1]

TABLE 222-1 SOME KNOWN FACTORS THAT INFLUENCE THE AGE AT MENOPAUSE

FACTOR	DIRECTION	DEGREE/COMMENT
GENETIC/FAMILIAL		
CYP3A4 and *CYP1B1*	Earlier menopause	Interaction with smoking
MSH6	Earlier menopause	Detected by GWAS
MCM8	Earlier menopause	Detected by GWAS
PvuII ER polymorphism	Earlier menopause, hysterectomy	6 mo
Mosaic Turner syndrome	Earlier menopause	Variable
Fragile X	Earlier menopause	Variable

DIAGNOSIS

The diagnosis of pyelonephritis during pregnancy is suspected with clinical findings of fever, flank pain manifest as costovertebral tenderness on examination, and urinary complaints. Patients present most commonly during the second trimester. The differential diagnosis includes labor, chorioamnionitis, appendicitis, and adnexal torsion. Following a careful history and physical examination, a catheterized urine collection should be obtained to avoid contamination from the lower genital tract. Urinalysis reveals bacteriuria, leukocytes, and nitrites. Urine and blood cultures should be obtained.

TREATMENT

Hospital admission is advised for suspected cases of pyelonephritis during pregnancy. Intravenous fluid support to preserve adequate urinary output is paramount. Empirical antibiotics targeting anticipated pathogens should be initiated promptly (Chapter 266).[32] Typical initial empirical regimens include either ceftriaxone (1 g every 24 hours) or ampicillin (1 g every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours). Intravenous antibiotics should then be tailored to culture results once available. Supportive care includes antipyretics, serial maternal assessment, and fetal monitoring for viable gestations. Notable alterations to maternal blood pressure, pulse, or respiratory function may be early indicators of urosepsis. In general, a mean arterial pressure of at least 65 mm Hg is needed to preserve maternal-fetal perfusion. If necessary despite fluid resuscitation, norepinephrine is the first-line vasopressor recommended during pregnancy (Chapter 94).[33] The clinical course is typically 3 to 4 days of recurrent spiking fevers but with gradual improvement in the temperature curve and peak fevers. For unresponsive infections after 3 to 4 days, genitourinary imaging with either sonography or magnetic resonance imaging is recommended to exclude nephrolithiasis, a perinephric abscess, or an anatomic abnormality that may be causing obstruction.

Following acute resolution of infection, intravenous antibiotics are typically transitioned to a 10- to 14-day course for outpatient management tailored to culture results. Thereafter, oral antibiotic suppression for the remainder of pregnancy is recommended because about one-third of women will have recurrent infection.

PREVENTION AND PROGNOSIS

Pregnant women should be screened for asymptomatic bacteriuria at least once during early pregnancy. Any infection should be treated (see Chapter 263), with a follow-up culture to ensure success. Beyond the immediate infection, neither mother nor fetus have any long-term sequelae treatment.

COVID-19

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Chapter 336) and the disease it causes (coronavirus disease 2019; COVID-19) puts pregnant women at increased risk for hospitalization and intensive care unit admission, and it puts their fetus at increased risk of preterm birth.[34,35] Management requires a multidisciplinary team. Delivery may not improve outcomes. Vaccination during pregnancy is highly protective against infection during pregnancy and is strongly recommended.[36]

222 MENOPAUSE

NANETTE SANTORO AND GENEVIEVE NEAL-PERRY

DEFINITION

Menopause is defined as the permanent cessation of menses and is the culmination of a process of reproductive aging that typically occurs in the fifth to sixth decades of life, with a median age of 52.5 years.

EPIDEMIOLOGY

Menopause is a universal phenomenon among women, and its lived experience varies by individual. The advent of menopause and the coincident loss of gonadal steroids significantly affect multiple organ systems in affected women, thereby resulting in an increased risk for osteoporosis (Chapter 225), dementia (Chapter 371), and heart disease (Chapter 40).

Many factors influence the timing of the final menstrual period for any given woman (Table 222-1). Knowing one's mother's age at her final menstrual period is a strong predictor of when a woman is likely to have her own.[1]

TABLE 222-1 SOME KNOWN FACTORS THAT INFLUENCE THE AGE AT MENOPAUSE

FACTOR	DIRECTION	DEGREE/COMMENT
GENETIC/FAMILIAL		
CYP3A4 and *CYP1B1*	Earlier menopause	Interaction with smoking

ABSTRACT

Menopause marks the end of a woman's reproductive life and the cessation of ovarian function. Unlike other endocrine deficiency syndromes, menopause is not a pathologic state per se, but both the transition into menopause and its aftermath of constitutively low sex steroid secretion are associated with changes in health outcomes that vary based on a number of modifiable (body mass index, socioeconomic status) and nonmodifiable (race/ethnicity) factors. The acute consequences of the menopause transition are mostly related to symptoms and their management: hot flashes, vaginal dryness, mood changes, and sleep disturbances are the predominant conditions that lead women to seek medical treatment. With progress through the menopausal transition, persistence of symptoms as well as complications of aging, such as cardiometabolic disease, bone demineralization, and cognitive decline, may lead to a need for short- or longer-term use of hormones or other agents, each with its own risks and benefits, to mitigate symptoms. Clinicians are encouraged to use shared decision making when recommending treatment of menopausal symptoms or the consequences of menopause with their patients.

TABLE 222-2 STAGING REPRODUCTIVE AGING

STAGE	REPRODUCTIVE (−5 to −3)	MENOPAUSAL TRANSITION (−2 to −1)		POSTMENOPAUSE (+1 to +2)
Subdivisions	Early, peak, late	Early (−2)	Late (−1)	Early, late
Age ranges (approximate)	13-47	47-49	49-52	50+
Menses	Mostly regular	Minor irregularity	≥60-364 days amenorrhea	Amenorrhea
Hormonal hallmarks	FSH—low (rises sporadically at stage −3) AMH—high	FSH sporadically elevated AMH—normal to low	FSH more consistently elevated AMH—low	FSH consistently elevated (>25 IU/L) AMH—undetectable

The diagram distills the evidence from the STRAW paradigm (Harlow SD, Gass M, Hall JE, et al. *J Clin Endocrinol Metab*. 2012;97:1159-1168) into a brief referable item to help "place" a woman along the menopause transition. Stage 0 is the final menstrual period. Clinically helpful milestones are mostly related to menstrual regularity. FSH or AMH can be used as confirmatory tests when clinical context is unclear. AMH = antimüllerian hormone; FSH = follicle-stimulating hormone.

The menopausal transition refers to the processes of reproductive aging (Table 222-2) that involve menstrual cycle change, irregularity, and a breakdown of typical reproductive hormonal patterns and feedback mechanisms that characterize the fertile cycles of midreproductive-age women. Patterns of the production of gonadal hormones are altered, such that cycles become shorter and more sporadic and display less progesterone production. Follicle-stimulating hormone (FSH) increases sporadically as the remaining ovarian follicular pool (ovarian reserve) requires more and more stimulation to produce a preovulatory follicle. Eventually, FSH cannot sustain folliculogenesis, so menses begin to skip. Because ovarian folliculogenesis waxes and wanes over the course of the transition, cycles do not stop abruptly. Instead, ovulatory and anovulatory cycles alternate in an apparently random fashion. The resulting hormonal fluctuations trigger the onset of bothersome and sometimes debilitating symptoms for many women.

Symptoms of menopause do not simply appear with the final menstrual period; rather, they are usually present throughout the transition, although they tend to intensify as women progress through the transition. For many women, symptoms begin in the early menopausal transition and worsen by the late transition through the early postmenopausal period.

Determining a woman's proximity to her final menstrual period has implications that are important for her health. Women with an early final menstrual period will spend a greater proportion of their lifetime in a state of relative hypogonadism, which has consequences on bone health and cognition as well as on cardiovascular health. Women whose transition is later are more prone to estrogen-related diseases, such as breast cancer (Chapter 183) and endometrial cancer (Chapter 184). Additionally, women who have not yet undergone 12 months of amenorrhea may wish to know when they can safely discontinue the use of contraception. Finally, many women who are symptomatic may want to predict how long their symptoms are likely to last.

PATHOBIOLOGY

Both menopause and advancing age impose adverse effects on central nervous system (CNS) function (Chapter 371). The brain is enriched with estrogen receptors, and estrogen receptor signaling is hypothesized to mediate multiple key processes in the CNS, including but not limited to neurotrophic effects and neuroprotection.[2] Menopause and advancing age both impose adverse effects on CNS function.

Sex differences in the structure and function of the hippocampus and the temporal lobe are hypothesized to relate to differences in the activational and organizational effects of estradiol on memory performance. Estrogen-mediated structural differences in the hypothalamic cytoarchitecture translate into higher executive functioning in women. Consequently, anxiety and mood changes are more common in perimenopausal and recently menopausal women, especially in women who have a history of mood dysfunction or adverse childhood experiences. Hypogonadism of menopause may explain why perimenopausal and early postmenopausal women frequently complain of memory loss and inability to focus. However, studies of hormone therapy in menopausal women provide conflicting results regarding its benefit on attention and executive functions such as nonspatial and spatial working memory, as well as verbal memory. Moreover, many of these executive functions spontaneously recover within a few years of the final menstrual period.

Bone health is significantly affected by gonadal steroids.[3] Over the menopausal transition, serum estradiol and estrone concentrations decrease by as much as 90%. This decline closely parallels a period of accelerated and progressive bone loss (Chapter 225). Reduced estrogen signaling in menopause disrupts the balance of receptor activator nuclear factor-κβ ligand (increased) and osteoprotegerin (decreased) concentrations, with the end effect being increased osteoclast activity, accelerated bone resorption, and attenuated bone remodeling. All of these changes result in significant increases in urinary and serum markers of bone resorption, as well as accelerated changes in bone mineral density in the late menopause transition. Annual rates of bone loss approximate 1.8 to 2.3% in the spine and 1.0 to 1.4% in the hip. As much as 30% loss of trabecular and 10% loss of cortical bone occurs over the 6 to 10 years spanning the perimenopausal and early menopausal period. Menopause-driven changes in bone physiology result in an increased risk for osteoporosis (Chapter 225) and a 50 to 100% higher fracture rate.

Increased weight gain and altered fat distribution are common complaints in perimenopausal and menopausal women regardless of race, ethnicity, or socioeconomic status. Midlife women gain approximately 2 to 5 pounds on average, though with wide variation, and exhibit significant changes in their body composition. Postmenopausal weight gain and increased central adiposity may in part reflect an effect of hypogonadism on the gut microbiota. Hypogonadism may affect adipose tissue, which is an endocrine organ that expresses estrogen receptors, by disrupting adipocyte lipolysis and adipogenesis.[4] Increased central adiposity is characterized by chronic low-grade inflammation, metabolic syndrome, and more than a four-fold increased risk in cardiovascular death. Additionally, obese perimenopausal and early menopausal women experience more frequent and severe hot flashes as well as sexual dysfunction.

CLINICAL MANIFESTATIONS

Menopause is a universal phenomenon among women, and its lived experience varies from person to person. The advent of menopause and the coincident loss of gonadal steroids affect multiple organ systems and can result in increased risk for morbidity related to osteoporosis, dementia, and heart disease.

Symptoms that women report as they traverse menopause may be difficult to disentangle from those related to aging itself. Four cardinal symptoms are considered to be directly related to menopause, based on their association with the transition and their ability to be treated with hormones. These include vasomotor symptoms/hot flashes, vaginal dryness, sleep disturbances, and mood/cognition problems.[5]

Vasomotor Symptoms

Vasomotor symptoms are experienced by up to 80% of women, at an average of 4.5 years after their final menstrual period and with a median duration of 7.4 years. Vasomotor symptoms are caused by aberrant activation of the tachykinin system. Women whose symptoms begin at an earlier age and who are earlier in their transition at onset have a longer duration of symptoms, with some women experiencing vasomotor symptoms for more than a decade. About 50% of women whose vasomotor symptoms precede entry into the menopausal transition often have persistent vasomotor symptoms for 10 years or longer after their final menstrual period. Black women are also more likely to have persistent vasomotor symptoms compared with other racial/ethnic groups; approximately 40% will report post–final menstrual period persistence of 10 years or longer. Additional factors that may result in a longer duration of vasomotor symptoms include lower educational level, greater perceived stress, more depressive symptoms, and anxiety at the time of the first report of vasomotor symptoms. Whereas a higher body mass index (BMI) at the time of early menopause is associated with more vasomotor symptoms, a higher BMI at the time of late menopause is associated with fewer vasomotor symptoms.

Genitourinary Symptoms

Vaginal dryness, dyspareunia,[6] and urogenital symptoms are less common than vasomotor symptoms but still prevalent in about 25 to 50% of menopausal women.[7] Women may report dryness, chronic irritation, or burning of both the vagina and vulva. Among those who are sexually active, lack of lubrication with attempted intercourse, pain during intercourse, or bleeding after intercourse may be present. Urinary frequency, urethritis, and frequent urinary tract infections (Chapter 263) may also occur. All of these symptoms are believed to reflect hypogonadism and the absence of estrogen exposure to the vaginal and urinary tract epithelium. Unlike vasomotor symptoms, symptoms of the genitourinary syndrome of menopause do not spontaneously resolve over time.

Sleep Disturbances

Sleep disturbances (Chapter 374) are more common in women but also worsen with age, so it can be challenging to differentiate between age-related changes compared with menopause.[8] Sleep architecture in menopausal women demonstrates greater sleep disturbances in the second half of the night, in association with compromise of rapid eye movement (REM) sleep. Whereas some epidemiologic studies indicate that the menopausal transition worsens preexisting sleep problems and is associated with worse sleep, others report little independent effect of ovarian failure on sleep, except for a small, vulnerable subset of women with relatively poor sleep at baseline. Studies of premenopausal women given a gonadotropin-releasing hormone (GnRH) agonist to produce abrupt estrogen withdrawal indicate significant alterations in sleep, largely related to subjective nighttime hot flashes that prompt nighttime awakenings.

An additional complexity in attributing sleep disturbances to menopause is the possibility that concomitant independent sleep disorders (e.g., insomnia, sleep apnea, and restless legs syndrome; Chapter 374) are present. Sleep apnea is suspected based on a history of snoring, daytime sleepiness, and less perceived restfulness of sleep, and it is diagnosed by an overnight sleep assessment. Diagnostic criteria for restless legs syndrome (Chapter 374) include irresistible urges to move one's legs; symptoms present at rest; urge relieved by movement; and peak symptoms at night or in the evening. Insomnia (see Table 374-5 and Fig. 374-6) may appear at the time of the menopausal transition, but it may also be long-standing in duration. Women age 35 years or over with insomnia have the highest rates of persistence of sleep disorders in menopause.

Mood Disorders

Adverse mood is associated with traversal of menopause in a complex manner. Abrupt estrogen withdrawal using a GnRH agonist in premenopausal women results in a deterioration of mood. Depressive symptoms are associated with nighttime hot flashes and sleep disruption, thereby indicating the intimate relationship between sleep and mood. Multiple cohort studies have identified the late transition as a period of vulnerability for depression in midlife women.[9] Women are two- to four-fold more likely to experience new onset of major depression (Chapter 362) during the menopausal transition than they are before they become perimenopausal or after their final menstrual period. Concomitant anxiety and hot flashes are predictors of major depression during this time of life. Although absolute levels of hormones are not clearly associated with major depression or depressive symptoms, greater variability in FSH, luteinizing hormone, and estradiol have been linked to depressive symptoms.

DIAGNOSIS

Menopause is a clinical diagnosis typically based on amenorrhea for at least 12 months.[10] However, this definition relies on a woman having menstrual cycles with some degree of regularity. Women who are age 45 or older have a 90% probability of never having another menstrual period once they attain the milestone of 12 months' amenorrhea. In contrast, younger women have a substantially greater probability of experiencing subsequent menses. The final menstrual period is most often preceded by several years of instability in menstrual cyclicity and hormone secretion. This process, which is called the menopausal transition, usually persists for about 4 years, but with wide variation around this median. Women who enter the transition at a younger age tend to have more symptoms and a longer transition, whereas women who enter it later in life are more likely to have a rapid transition to their final menstrual period.

No diagnostic test can definitively predict when a woman will have her final menstrual period. Nonetheless, the serum level of antimüllerian hormone, which is a transforming growth factor beta family peptide synthesized by granulosa cells, is a reliable proxy of ovarian reserve (remaining follicle volume) and can be used to help approximate the timing of the final menstrual period.[11] Other measures, such as levels of FSH or the inhibins, are generally not recommended for this purpose, in part because—unlike antimüllerian hormone—they fluctuate throughout the menstrual cycle.

TREATMENT

Current guidelines for menopausal management concur that only symptomatic treatment, as needed, is indicated for this normal life transition. Clinicians should assess the patient's symptoms and offer evidence-based treatment, with periodic reevaluation of the necessity of treatment.

Whereas the need for treatment of hot flashes, sleep problems, and mood problems will very likely decrease over time, a minority of women will continue to have significant symptoms and require long-term treatment, either with extended hormonal therapy or nonhormonal alternatives. Genitourinary symptoms are long lasting, so long-term treatment may be necessary.

Symptoms most commonly associated with menopause (hot flashes, sleep dysfunction, mood, and genitourinary syndrome of menopause) are readily improved with hormone therapy. However, fear of hormones has led to widespread undertreatment of symptoms and a proliferation of nonrigorously tested but popular treatments, such as a large variety of herbal preparations.

Vasomotor Symptoms

Nonhormonal management of menopausal symptoms can include nonpharmacologic and pharmacologic methods. For mild to moderate symptoms, behavioral and nonpharmacologic approaches may be preferred. However, for more severe symptoms, pharmacologic management typically will be required.

Behavioral and Nonpharmacologic Approaches

Women may experience hot flash "triggers" from caffeine or alcohol and may modify consumption accordingly. Reducing the ambient room temperature and layering clothing to accommodate sudden changes in heat perception may also be helpful, but these recommendations are not based on medical evidence. Cognitive-behavioral therapy, which has demonstrated 50% efficacy in the treatment of hot flashes in women with breast cancer, has negligible potential for harm and can be recommended for all symptomatic menopausal women.

Weight loss has shown some efficacy in observational studies. Acupuncture has some evidence for efficacy, but not all trials have demonstrated benefit.[A1] Yoga, exercise, and consumption of black cohosh and omega-3 fatty acids have been demonstrated to be ineffective in several randomized trials.

Nonhormonal Medications

A number of nonhormonal prescription medications (Table 222-3) can be used to treat hot flashes for women who cannot or do not wish to use hormones.[12] Although many of these treatments are supported by well-conducted randomized, clinical trials, only paroxetine mesylate and fezolinetant are FDA approved as of this writing. Experimental nonhormonal agents targeting the neurokinin-3 receptor appear to have great specificity for the treatment of hot flashes and an efficacy that is comparable to estrogen.[A2]

Systemic Hormonal Therapy

Systemic hormonal therapy should be reserved for women with bothersome vasomotor symptoms.[13,14] Observational data as well as randomized clinical trials suggest that hormone therapy, when administered within the first 5 years of the final menopause, attenuates some, but not all, of the adverse effects of menopause-related hypogonadism.

Hormonal therapies include estradiol, estrogens, and, when women have a uterus, progestin (Table 222-4).[15] Risks and side effects of hormonal therapy are modulated by the route of administration, hormonal formulation, age, time since the final menstrual period, and the presence or absence of a uterus, as well as coexisting comorbid conditions, such as cardiovascular disease, dementia, and diabetes.[16] Approved prescription medications are preferred over compounded hormone products, which lack adequate data on efficacy and safety.

For women who cannot or do not wish to take estrogen, oral micronized progesterone in daily doses up to 300 mg per day has demonstrated efficacy in the treatment of hot flashes.[A3] Long-term risks and benefits are not known at this time.

Uterine neoplasia is increased under conditions of chronic unopposed estrogen exposure in a woman with an intact uterus. Thus, the primary indication of progestin therapy during menopause is to prevent estradiol-induced endometrial hyperplasia and cancer. Commonly used progestins include medroxyprogesterone acetate, norethindrone acetate, and micronized progestin (native progesterone). Progestin administered continuously or sequentially provides adequate endometrial protection. However, controversy exists as to whether micronized progestin protects the uterus as effectively as synthetic progestin.

Risks of Systemic Hormone Therapy

In the Women's Health Initiative study, the combined estrogen/progestin therapy arm was stopped prematurely after 5.2 years because of increased hazard ratios for coronary heart disease (1.29), breast cancer (1.26), stroke (1.41),

TABLE 222-3 NONHORMONAL PHARMACOLOGIC THERAPY FOR HOT FLASHES

MEDICATION	USUAL DAILY DOSES	RELATIVE EFFICACY†	SIDE EFFECTS
Citalopram	20-40 mg	50%	Nausea, somnolence or insomnia, dry mouth, dyspepsia
Clonidine	Transdermal: 0.1-0.2 mg Oral: 0.1-0.3 mg	30%	Dry mouth, orthostatic hypotension, dizziness
Desvenlafaxine	100-150 mg	60%	Nausea, dry mouth, insomnia/somnolence, constipation, high blood pressure, sexual dysfunction
Escitalopram	10-20 mg	50%	Nausea, insomnia, headache, sexual dysfunction
Fezolinetant	45 mg	?	Hepatotoxicity, abdominal pain, diarrhea
Fluoxetine	10-20 mg	50%	Nausea, insomnia, headache, sexual dysfunction
Gabapentin	100-900 mg	60%	Drowsiness, dizziness, weight gain
Paroxetine mesylate*	7.5 mg	30%	Nausea, insomnia, headache, sexual dysfunction
Venlafaxine	37.5-150 mg	60%	Nausea/vomiting, anorexia, dry mouth, sexual dysfunction, high blood pressure

*Food and Drug Administration approved.
†Relative efficacy: estimated effectiveness compared with estrogen.

TABLE 222-4 POSTMENOPAUSAL HORMONE OPTIONS FOR VASOMOTOR SYMPTOMS*

DRUG	SUGGESTED FORMULATIONS	USUAL DOSAGE
ORAL ESTROGEN/PROGESTOGEN COMBINATIONS†		
Conjugated estrogen/medroxyprogesterone (Prempro)	0.3/1.5, 0.625/2.5 mg tabs	0.3/1.5-0.625/5 mg PO once/d
Estradiol/drospirenone (Angeliq)	0.5/0.25, 1/0.5 mg tabs	0.5/0.25 or 1/0.5 mg PO once/d
Estradiol/norethindrone (Activella)	0.5/0.1, 1/0.5 mg tabs	0.5/0.1 or 1/0.5 mg PO once/d
Estradiol/progesterone (Bijuva)	1/100 mg caps	1/100 mg PO once/d
Ethinyl estradiol/norethindrone (Femhrt)	2.5 µg/0.5 mg tabs	2.5 µg/0.5 mg or 5 µg/1 mg PO once/d
ORAL ESTROGENS		
Conjugated estrogen (Premarin)	0.3, 0.625 mg tabs	0.3-0.625 mg PO once/d
Estradiol	0.5, 1 mg tabs	0.5-1 mg PO once/d
Esterified estrogen (Menest)	0.3, 0.625, 1.25 mg tabs	0.625-1.25 mg PO once/d
ORAL PROGESTOGENS		
Progesterone (micronized)	100 mg caps	100 mg PO once/d
Medroxyprogesterone	5, 10 mg tabs	5-10 mg PO once/d x 12-14 d/mo
TRANSDERMAL ESTROGENS		
Estradiol patches (Alora, Climara, or Vivelle)	0.05 mg/d patches	0.05 mg/d patch 1-2 x/wk
Estradiol gel (EstroGel, Divigel, or Elestrin)	0.75 mg/actuation (30 doses/unit) 0.25, 0.5, 0.75, 1 mg/packets 0.52 mg/actuation (100 doses/unit)	0.75 mg applied once/d 0.25-1 mg applied once/d 0.52 mg applied once/d
Estradiol transdermal spray (Evamist)	1.53 mg/spray (56 sprays/unit)	2 sprays once/d
VAGINAL ESTROGEN		
Estradiol intravaginal ring (Femring)	90-day vaginal ring	0.05 mg/d
TRANSDERMAL ESTROGEN/PROGESTIN COMBINATIONS		
Estradiol/levonorgestrel (Climara Pro)	0.045/0.015 mg/d patches	0.045/0.015 mg/d patch once/wk
Estradiol/norethindrone (CombiPatch)	0.05/0.14, 0.05/0.25 mg/d patches	0.05/0.14 or 0.05/0.25 mg/d patch 2 x/wk

*Brand names listed only when generic options are not available.
†For women with an intact uterus, estrogen plus progestogen is recommended.
d = day; mo = month; PO = orally; wk = week.

and pulmonary embolism (2.13), as well as increased risks for cognitive dysfunction, bone disease, and gastrointestinal cancer.[A4] However, long-term follow-up showed no differences in overall mortality at 18 years.[A5] A secondary analysis of Women's Health Initiative data comparing placebo with estrogen alone, however, found a statistically significant 18% reduction in the combined incidence of coronary heart disease, invasive breast cancer, stroke, pulmonary embolism, colorectal cancer, endometrial cancer, hip fracture, and all-cause mortality[A6] in women 50 to 59 years of age who had previously undergone a hysterectomy.

Risks of Coronary Heart Disease

Premenopausal women are at reduced risk for cardiovascular events compared with age-matched men and postmenopausal women,[17] thereby suggesting that estradiol may mediate the cardioprotection observed in premenopausal women. In addition to the Women's Health Initiative, relevant data from two smaller randomized trials also suggest cardiovascular safety for postmenopausal estrogen therapy. In one trial, conjugated equine estrogen or transdermal estradiol (with added sequential micronized progesterone) begun 6 to 36 months postmenopause did not increase carotid intima-media thickness, coronary artery calcium, cardiovascular events, venous thromboembolism, or breast or endometrial cancer. In another trial of postmenopausal women, 1 mg oral estradiol plus sequential vaginal progesterone (45 mg) therapy begun within 6 years of menopause was associated with decreased progression of carotid intima-media thickness and coronary artery calcium, whereas hormone therapy begun more than 10 years after menopause was no different than placebo.[A7] Taken together, these data suggest that women who initiate hormone therapy within 5 to 6 years of their final menstrual period are unlikely to experience an increase in risk of coronary heart disease as a result of treatment.

The risk of ischemic stroke (Chapter 376) is also increased with the use of hormone therapy. The risk for stroke is greatest with oral estrogen use and in women who have thrombophilia.

Risks of Venous Thromboembolic Disease

The use of oral estrogen increases the risk for venous thromboembolism (Chapter 68). Moreover, the risk for venous thromboembolism is increased whether it is estrogen-only or combined estrogen and progestin hormone therapy. The risk for thromboembolism, which increases with advancing age and is related to the estrogen dose, is higher within the first year of hormone therapy and magnified if a preexisting risk factor, such as obesity or thrombophilia, is present. The risk of venous thromboembolism is not significantly affected by micronized progesterone, medroxyprogesterone acetate, or norethindrone, but it is increased by norpregnane derivatives.

Risks of Cognitive Dysfunction

In the Women's Health Initiative Memory Study, the incidence of dementia (Chapter 371) was increased in women over age 65 years who initiated hormone therapy, but reduced global cognitive function was not observed when women 50 to 55 initiated hormone therapy. Other clinical trials also suggest that hormone therapy taken by younger women in early menopause does not adversely affect cognitive function. Whether early intervention with hormone therapy provides long-term cognitive benefit is currently under investigation.[18]

Risk of Breast Cancer

Combined estrogen and progestin menopausal therapy increases the risk of breast cancer (Chapter 183) compared with estrogen alone. For example, in the Women's Health Initiative study, combined equine estrogen and medroxyprogesterone acetate caused a nonsignificant increased risk for invasive breast cancer after 3 years, which became significant after 5+ years and remained elevated at 13 years in the postintervention study.[A8] In a French cohort study, the risk of breast cancer was significantly increased in women who used a progestin other than progesterone or dydrogesterone and in women who reported more than 5 years of menopausal hormone use. By comparison, estrogen-only menopausal hormone therapy has had a less consistent effect on the risk for breast cancer. In the Women's Health Initiative study, for example, the risk of breast cancer was 22% lower with estrogen alone in women with a prior hysterectomy compared with the increased risk associated with combined hormone therapy in women with an intact uterus.[A9] These data suggest a link between treatment with progestin and an increased risk for breast cancer.

Extending or Discontinuing Hormone Therapy

Menopausal symptoms appear to be subjectively worst in the year before the final menstrual period and up to 2 years afterward, and many women choose to discontinue hormones after the worst of their menopausal symptoms have subsided. For the majority of women, hormone doses may be reduced, or they may attempt to discontinue either by weaning slowly off of hormones or by stopping "cold turkey." There is limited evidence to suggest that a weaning strategy is less disruptive, but it does not necessarily lead to a greater proportion of women who successfully discontinue hormone therapy.

Additionally, the risks and benefits of hormone therapy vary by organ system, the hormone therapy formulation, and the time since the final menstrual period. Observational as well as randomized clinical trials also suggest that hormone therapy, when administered within the first 5 years of final menopause, attenuates some, but not all, of the adverse effects of menopause-related hypogonadism.[19]

Women who use combined estrogen and progestin hormone therapy for more than 5.6 years have an increased risk of invasive breast cancer, and women who continue use beyond 4 to 5 years should be monitored carefully. However, hormones need not be discontinued for many healthy women, as long as they continue to serve a purpose, especially for women who are approaching 5 to 10 years on hormone therapy but continue to have severe symptoms. Such women should be tried on nonhormonal options, but extended hormone therapy may be needed to preserve quality of life if they cannot be weaned. A small proportion of women, estimated at 3 to 15%, will have lifelong persistence of severe symptoms and will require continued hormones or nonhormonal alternatives.

Uterine neoplasia (Chapter 184) is increased under conditions of chronic unopposed estrogen exposure in a woman with an intact uterus, so the primary indication for progestin therapy during menopause is to prevent estradiol-induced endometrial hyperplasia and cancer. Commonly used progestins include medroxyprogesterone acetate, norethindrone acetate, and micronized progestin (native progesterone). Progestin treatment is most often achieved with combined estrogen and progesterone formulations (Table 222-4). Alternatively, progestin administered continuously (100 mg micronized progesterone or 2.5 mg of medroxyprogesterone) or sequentially (200 mg micronized progesterone or 5 mg medroxyprogesterone) provides adequate endometrial protection, but controversy exists as to whether micronized progestin protects the uterus as effectively as synthetic progestin (Chapter 184).

Vaginal Symptoms

Unlike hot flashes, symptoms of vaginal atrophy, including urinary tract irritation, vaginal itching and burning, and dyspareunia (collectively referred to as genitourinary syndrome of menopause), do not subside over time. Therefore long-term treatment may be required to preserve quality of life.[20]

For vaginal symptoms or the genitourinary syndrome of menopause, vaginal moisturizers (which must be used regularly to achieve effectiveness) and vaginal lubricants, which are specifically helpful during intercourse, can be recommended.[21-23] A vaginal hyaluronidase-based gel is as efficacious as 10-μg estradiol tablets twice weekly for relief of the most bothersome symptom.[A10] Little attention has been paid to the exact composition of these products, which are available over the counter. Women should be advised to choose products that are pH balanced (i.e., relatively acidic) with a physiologic osmolality.

Fortunately, long-term use of local estrogen compounds appears to be safe and well tolerated (Table 222-5). Systemic absorption of estrogen through vaginal administration of pills, capsules, and rings is minimal, but vaginal creams are more likely to increase circulating estradiol levels temporarily. Dehydroepiandrosterone can be used vaginally to treat dyspareunia. Ospemifene, a selective estrogen receptor modulator that has estrogen receptor beta stimulation properties, is available as a nonestrogenic treatment; however, it is administered systemically. Laser treatment of the vagina does not improve the symptoms of the genitourinary syndrome of menopause.[A11]

Sleep and Mood Disorders

Nonhormonal treatment of adverse mood includes psychotherapy and antidepressants (Table 362-5), with or without antianxiety medication (Table 362-9) as needed. For moderate to severe mood disturbances, hormonal therapy should not be used as a first-line treatment.

Difficulty sleeping can be addressed behaviorally. Telephone-based cognitive-behavioral therapy can benefit about 85% of postmenopausal women with moderate insomnia.[A12] A self-help smartphone app (https://mobile.va.gov/app/cbt-i-coach) is available to enable patients to implement such treatment. For patients who wish to use over-the-counter treatments, diphenhydramine (25 to 50 mg) or hydroxyzine (25 to 100 mg at bedtime) may facilitate the onset of sleep. A low-dose melatonin receptor agonist (ramelteon 4 mg at bedtime) may be effective in reducing sleep-onset latency, although high-quality clinical trials are lacking in a menopausal population. Judicious, short-term use of a variety of hypnotics and melatonin receptor agonists (Table 374-7) are available for the treatment of insomnia.

Mood and sleep issues are often intertwined, and treatment that addresses one of these conditions is likely to affect the other. To make matters more complex, hot flashes or night sweats that interrupt sleep can be a contributing factor to deteriorations of both mood and sleep. For example, citalopram is better than venlafaxine for reducing hot flashes (see Table 222-3), but venlafaxine is better for improving depression.[A13] It can be difficult to disentangle these overlapping contributory factors to adverse mood in a clinical setting. When symptoms are compound or overlapping, a brief trial of hormone therapy, if possible, may be better than using multiple agents specific for mood, sleep, and hot flashes to determine which symptoms are due to the menopausal transition and which are independent of it.

PREVENTION

Cardiovascular Risk

Postmenopausal women generally have cardiovascular risks equivalent to men who are about a decade older, and cardiovascular disease is the leading cause of death in elderly women. Postmenopausal women should be screened for hypertension (Chapter 64) and hyperlipidemia (Chapter 190), with the goal of reducing their subsequent risk for atherosclerosis (Chapter 40).[24] Based on current evidence, postmenopausal hormone therapy is not recommended to reduce cardiovascular risk.

Osteoporosis

Postmenopausal women have a markedly increased risk of bone loss and osteoporosis.[25] The preventive approach is covered in detail in Chapter 225. Based on current evidence, postmenopausal hormone therapy is not recommended to prevent osteoporosis.

PROGNOSIS

The need for treatment of hot flashes, sleep problems, and mood problems decreases over time, but a minority of women will continue to have significant symptoms and require long-term treatment, either with extended hormonal therapy or nonhormonal alternatives. The symptoms of the genitourinary syndrome of menopause are long lasting, and long-term treatment may be necessary. Clinicians should continuously assess the patient's symptoms and offer evidence-based treatment, with periodic reevaluation of the necessity of treatment.

TABLE 222-5 MEDICATION OPTIONS FOR GENITOURINARY SYNDROME OF MENOPAUSE*

DRUG	FORMULATION	SUGGESTED DOSE	COMMENTS
LOCAL VAGINAL THERAPY			
Estradiol (Estring)	2 mg ring (7.5 μg/d)	7.5 μg/d	Ring remains in place continuously for 90 days
Estradiol	10 μg insert	10 μg once/d × 2 wk, then 2 ×/wk	Single-use applicator containing one tablet
Prasterone (Intrarosa)	6.5 mg insert	6.5 mg qHS	-
Estradiol	0.1 mg/g cream	2 g once/d × 1-2 wk, then 1 g once/d × 1-2 wk	1 g after vaginal mucosa restored, 1-3 ×/wk
Conjugated estrogen (Premarin)	0.625 mg/g cream	0.5-2 g once/d × 3 wk followed by 7 d off, or 0.5 g 2 ×/wk	-
Estradiol vaginal inserts (Imvexxy)	4 μg and 10 μg	4 or 10 μg twice weekly	-
SYSTEMIC ORAL THERAPY			
Ospemifene (Osphena)	60 mg tabs	60 mg once/d	-

*Low-dose vaginal estrogen preferred for women who have only genitourinary symptoms. Brand names given only when generic options are not available.
d = day; qHS = at bedtime; wk = week.

223 INTIMATE PARTNER VIOLENCE

GENE FEDER AND HARRIET L. MACMILLAN

DEFINITION

Intimate partner violence is defined as any behavior that is within an intimate relationship or ex-relationship and that causes physical, psychological, or sexual harm.[1] Such behaviors can include physical aggression, such as hitting, kicking, and beating; psychological violence, such as intimidation or constant humiliation; various controlling behaviors, such as isolation from family and friends, monitoring movements, financial control, and restricting access to services; and sexual violence, including forced intercourse and other sexual coercion. Intimate partner violence is a gendered problem. Lifetime prevalence of isolated violent acts within relationships is comparable for men and women, but repeated coercive, sexual, or severe physical violence is perpetrated largely against women by men. Intimate partner violence is also experienced at high rates by sexual minorities,[2] and transgender individuals (Chapter 214) appear to be at higher risk compared with cisgender individuals.[3] Although intimate partner violence is present in all demographic groups, its prevalence is greater in lower socioeconomic groups globally.[4]

Historically, the stereotype was a male batterer who used severe, repeated, and unilateral violence against a nonviolent female victim, but *bilateral violence* is common, even though the overwhelming burden of morbidity and mortality related to intimate partner violence is experienced by women. Bilateral violence, sometimes referred to as *common couple violence*, is considered less severe than the pattern of abuse known as *battering* or *intimate terrorism*—a severe and escalating form of intimate partner violence characterized by threats, terrorization, multiple forms of abuse, and controlling behavior. Current data indicate that women rarely subject men to battering.

Intimate partner violence is a risk factor for a wide range of medical and psychiatric conditions that require a clinical and public health response. Intimate partner violence is a violation of human rights and a preventable public health problem that must be addressed through social and educational policies.

EPIDEMIOLOGY

The prevalence of intimate partner violence against women varies internationally,[5] but worldwide about 25% of ever-married or partnered women report having been subjected to physical and/or sexual violence at least once in their lifetime from a current or former husband or male intimate partner.[6] The likelihood of intimate partner violence is higher among women with non-White racial/ethnic identities.[7] Indigenous women also are at higher risk, in part owing to colonization, structural violence, racism, and discrimination.[8] Globally, about one in seven homicides is committed by an intimate partner, with the rate six times higher for female homicide victims compared with male homicide victims.[9]

PATHOBIOLOGY

The ecologic model attempts to integrate evidence on individual (genetic and life course), family, community, and societal factors. Most research has focused on factors associated with increased risk for women who experience violence from men (Table 223-1), but it is difficult to determine causality because data are obtained overwhelmingly from cross-sectional studies.

Social learning theory suggests that intimate partner violence is a learned behavior. Male perpetrators and female victims are more likely to report histories of exposure to violence in childhood, but most individuals exposed to violence in childhood do not go on to commit violence as adults, and not all who commit abuse have violent upbringings. Furthermore, the link between poor parenting generally, including neglect, and subsequent intimate partner violence in adulthood suggests that the effect is not simply one of modeling abusive behavior. Exposure to rejecting or neglectful parenting is associated with adverse effects on intrapersonal (e.g., poor self-worth) and interpersonal development, which are associated with intimate partner violence.

A feminist perspective understands intimate partner violence against women as a form of coercive control rooted in society's patriarchal structure and reflecting the persistent inequality in economic and social relationships between men and women. Lending support to this perspective is the finding that intimate partner violence appears to be less common in more democratic and less economically polarized societies. Although intimate partner violence occurs more often in contexts in which there is support for male authority in the family and in which women have less access to economic security, it is not clear why some individuals are more likely to be violent under such conditions than others.

Evidence is conflicting regarding an association between intimate partner violence and psychopathology. Abusive males may have deficits in one or more coping mechanisms, anger control, and communication skills, but intimate partner violence also can result from dysfunctional interactional patterns between partners.[10] Because types of intimate partner violence are not the same for all couples, there are likely multiple causes for its occurrence.

CLINICAL MANIFESTATIONS

Patients seldom present with a complaint of intimate partner violence. Injuries are the most obvious manifestation, and a clinician should have increased suspicion for intimate partner violence if a patient has multiple injuries, if the presenting history of injuries is not consistent with the physical examination, and if a delay has occurred before seeking medical care for injuries. Patients exposed to physical violence may present with injuries that vary from minor abrasions to life-threatening trauma. Although there can be overlap between injuries resulting from intimate partner violence and injuries from other causes, the former typically involve trauma to the head, face, and neck, whereas the latter are more typically injuries of the extremities. Multiple facial injuries are suggestive of intimate partner violence rather than other causes, and injuries that are more specific for intimate partner violence include zygomatic complex fractures, orbital blow-out fractures, and perforated tympanic membrane. Although facial injuries are the most common injuries associated with intimate partner violence, they have low specificity. Musculoskeletal injuries, which are the second most common type of injuries, include sprains, fractures, and dislocations. Blunt force trauma to the forearms should raise suspicion of intimate partner violence because it can occur when trying to block being struck.

223 INTIMATE PARTNER VIOLENCE

GENE FEDER AND HARRIET L. MACMILLAN

DEFINITION

Intimate partner violence is defined as any behavior that is within an intimate relationship or ex-relationship and that causes physical, psychological, or sexual harm.[1] Such behaviors can include physical aggression, such as hitting, kicking, and beating; psychological violence, such as intimidation or constant humiliation; various controlling behaviors, such as isolation from family and friends, monitoring movements, financial control, and restricting access to services; and sexual violence, including forced intercourse and other sexual coercion. Intimate partner violence is a gendered problem. Lifetime prevalence of isolated violent acts within relationships is comparable for men and women, but repeated coercive, sexual, or severe physical violence is perpetrated largely against women by men. Intimate partner violence is also experienced at high rates by sexual minorities,[2] and transgender individuals (Chapter 214) appear to be at higher risk compared with cisgender individuals.[3] Although intimate partner violence is present in all demographic groups, its prevalence is greater in lower socioeconomic groups globally.[4]

Historically, the stereotype was a male batterer who used severe, repeated, and unilateral violence against a nonviolent female victim, but *bilateral violence* is common, even though the overwhelming burden of morbidity and mortality related to intimate partner violence is experienced by women. Bilateral violence, sometimes referred to as *common couple violence*, is considered less severe than the pattern of abuse known as *battering* or *intimate terrorism*—a severe and escalating form of intimate partner violence characterized by threats, terrorization, multiple forms of abuse, and controlling behavior. Current data indicate that women rarely subject men to battering.

Intimate partner violence is a risk factor for a wide range of medical and psychiatric conditions that require a clinical and public health response. Intimate partner violence is a violation of human rights and a preventable public health problem that must be addressed through social and educational policies.

EPIDEMIOLOGY

The prevalence of intimate partner violence against women varies internationally,[5] but worldwide about 25% of ever-married or partnered women report having been subjected to physical and/or sexual violence at least once in their lifetime from a current or former husband or male intimate partner.[6] The likelihood of intimate partner violence is higher among women with non-White racial/ethnic identities.[7] Indigenous women also are at higher risk, in part owing to colonization, structural violence, racism, and discrimination.[8] Globally, about one in seven homicides is committed by an intimate partner, with the rate six times higher for female homicide victims compared with male homicide victims.[9]

PATHOBIOLOGY

The ecologic model attempts to integrate evidence on individual (genetic and life course), family, community, and societal factors. Most research has focused on factors associated with increased risk for women who experience violence from men (Table 223-1), but it is difficult to determine causality because data are obtained overwhelmingly from cross-sectional studies.

Social learning theory suggests that intimate partner violence is a learned behavior. Male perpetrators and female victims are more likely to report histories of exposure to violence in childhood, but most individuals exposed to violence in childhood do not go on to commit violence as adults, and not all who commit abuse have violent upbringings. Furthermore, the link between poor parenting generally, including neglect, and subsequent intimate partner violence in adulthood suggests that the effect is not simply one of modeling abusive behavior. Exposure to rejecting or neglectful parenting is associated with adverse effects on intrapersonal (e.g., poor self-worth) and interpersonal development, which are associated with intimate partner violence.

A feminist perspective understands intimate partner violence against women as a form of coercive control rooted in society's patriarchal structure and reflecting the persistent inequality in economic and social relationships between men and women. Lending support to this perspective is the finding that intimate partner violence appears to be less common in more democratic and less economically polarized societies. Although intimate partner violence occurs more often in contexts in which there is support for male authority in the family and in which women have less access to economic security, it is not clear why some individuals are more likely to be violent under such conditions than others.

Evidence is conflicting regarding an association between intimate partner violence and psychopathology. Abusive males may have deficits in one or more coping mechanisms, anger control, and communication skills, but intimate partner violence also can result from dysfunctional interactional patterns between partners.[10] Because types of intimate partner violence are not the same for all couples, there are likely multiple causes for its occurrence.

CLINICAL MANIFESTATIONS

Patients seldom present with a complaint of intimate partner violence. Injuries are the most obvious manifestation, and a clinician should have increased suspicion for intimate partner violence if a patient has multiple injuries, if the presenting history of injuries is not consistent with the physical examination, and if a delay has occurred before seeking medical care for injuries. Patients exposed to physical violence may present with injuries that vary from minor abrasions to life-threatening trauma. Although there can be overlap between injuries resulting from intimate partner violence and injuries from other causes, the former typically involve trauma to the head, face, and neck, whereas the latter are more typically injuries of the extremities. Multiple facial injuries are suggestive of intimate partner violence rather than other causes, and injuries that are more specific for intimate partner violence include zygomatic complex fractures, orbital blow-out fractures, and perforated tympanic membrane. Although facial injuries are the most common injuries associated with intimate partner violence, they have low specificity. Musculoskeletal injuries, which are the second most common type of injuries, include sprains, fractures, and dislocations. Blunt force trauma to the forearms should raise suspicion of intimate partner violence because it can occur when trying to block being struck.

ABSTRACT

Intimate partner violence, which is a violation of human rights, is defined as any behavior within an intimate relationship or ex-relationship that causes physical, psychological, or sexual harm, including physical aggression, psychological violence (such as intimidation, constant humiliation), controlling behaviors (such as restricting access to services), and sexual violence. Intimate partner violence is present in all societies, with over a 25% global lifetime prevalence in women. Although intimate partner violence can occur in any intimate relationship, it is a gendered problem that disproportionately affects women and gender and sexual minorities. Although usually less severe than in women, intimate partner violence experienced by men also increases the risk of health problems and injuries. Although injury is the most obvious clinical manifestation of intimate partner violence, most people who experience intimate partner violence do not present to health care providers with signs of obvious trauma but rather with a constellation of overlapping physical and mental health problems. These conditions may persist even when the abuse ends—particularly chronic pain, gynecologic problems, anxiety, depression, and post-traumatic stress disorder. Universal screening for intimate partner violence is not recommended in health care settings, but clinicians should have a low threshold for asking about abuse and should know how to respond appropriately and safely, including how to facilitate referral to a specialist resource that can offer advocacy and further support. Women survivors of intimate partner violence benefit from advocacy and from trauma-informed psychological treatment.

TABLE 223-1 RISK FACTORS ASSOCIATED WITH EXPERIENCING INTIMATE PARTNER VIOLENCE

INDIVIDUAL	RELATIONSHIP	COMMUNITY	SOCIETAL
Experiencing child maltreatment	Poor family functioning	Weak community sanctions against intimate partner violence	Gender-inequitable social norms
Less than high school education among parents	Relationship instability	Poverty	Lack of women's civil rights, including restrictive or inequitable divorce and marriage laws
Young age	Relationship conflict	Economic inequality	Broad social acceptance of violence as a way to resolve conflict
Unplanned pregnancy	Male dominance	Low social capital	High levels of general violence in society, including armed conflict
Harmful use of drugs and alcohol	Educational disparity where a woman has a higher level than her male partner		
Past history of abusive partners	Economic stress		
Low socioeconomic status			

Victims of intimate partner violence often experience multiple mechanisms of injury; being struck by a hand is the most common, followed by use of a household object. Injuries from weapons such as knives and guns are far less common (<1%) but are associated with higher risk of mortality. Attempted strangulation occurs frequently. Other injuries that raise suspicion of intimate partner violence include fractures of the spine or trunk, bites, hair pulling, and open wounds. Patients who are exposed to sexual abuse may show signs of trauma to the genital area, but sexual assault is associated with signs of injury in less than one third of cases.

Most victims of intimate partner violence present to health care settings with overlapping physical and mental health problems rather than signs of obvious trauma. A patient who presents with vague signs and symptoms or chronic somatic complaints, including pain, suggests the possibility of intimate partner violence. Other behaviors that suggest intimate partner violence include delay in seeking medical care, multiple cancellations of medical appointments, or a partner insisting on being present throughout the consultation.

Other physical conditions that should raise suspicion of intimate partner violence include chronic gynecologic or gastrointestinal symptoms, such as chronic pelvic pain or irritable bowel syndrome. Intimate partner violence is associated with an increased risk for sexually transmitted infections, including HIV/AIDS, as well as sexual reproductive dysfunction.

Regardless of sex or gender, victims of intimate partner violence experience an increased risk of poor health as well as chronic physical and emotional health problems and injuries. Exposure to any type of intimate partner violence, whether physical or psychological, can be associated with a wide range of emotional and behavioral symptoms; depression and post-traumatic stress disorder (PTSD) are the two most commonly associated emotional conditions, but anxiety disorders and substance use disorders are also associated with intimate partner violence (Chapter 362). Women who reported intimate partner violence at least once in their lives also reported three to four times more emotional distress, suicidal thoughts, and suicide attempts than nonabused women. The relationships appear to be bidirectional, with depressive symptoms, substance use, and depression as both risk factors and outcomes of intimate partner violence.[11,12] Women who have experienced intimate partner violence have increased rates of chronic physical conditions, particularly gynecologic, gastrointestinal, and nervous system disorders; cancer; cardiovascular disease; type 2 diabetes; and all-cause mortality,[13] but a cause-and-effect relationship between intimate partner violence and these medical conditions is not established.

Intimate partner violence may begin, increase, or decrease during pregnancy, and it is more likely if the pregnancy was unplanned or unwanted. Abuse directed to the abdomen may lead to poor pregnancy outcomes and perinatal death. Intimate partner violence is associated with negative effects on parenting, including lack of effective parenting skills, increased aggression, and diminished communication.[14] Additionally, a child's exposure to intimate partner violence is significantly associated with the child's internalizing and externalizing problems, including trauma symptoms, developmental delay, educational problems, and long-term mental health conditions. These sequelae are consistent with a cycle of abuse, with child abuse leading to increased violence against women and additional child maltreatment, which in turn increases the risk of adult violence.

DIAGNOSIS

Universal screening for intimate partner violence increases the identification of affected women[A1] but has not been shown to improve women's health outcomes or reduce the occurrence of intimate partner violence.[15] However, clinicians must be alert to the signs and symptoms associated with intimate partner violence, including the broad range of physical and mental health conditions, and have a low threshold for asking about abuse. When possible indicators are present, the clinician should begin with the presenting concern, followed by general questions about the patient's well-being, before asking about safety in the home. When asking about exposure to intimate partner violence, it is important to do so privately, with no one else present, including a child (beyond infancy) or partner. If the inquiry or response is overheard, it could put the patient at risk for further intimate partner violence.

Learning modules[16] that include scripts, "how-to videos," and interactive scenarios about how clinicians can recognize and respond safely to intimate partner violence can help guide the evaluation. Before asking specific questions, the patient should be advised about any limits of confidentiality, including the requirement for mandatory reporting in some jurisdictions, when a patient has children in the home. When the topic of intimate partner violence is raised, patients want questioning that is nonjudgmental, compassionate, and caring. Women want to be asked about intimate partner violence, but they do not want to be pressured to disclose.

Possible questions to ask if intimate partner violence is suspected include: (1) Sometimes partners or ex-partners use physical force. Has this ever happened to you? (2) Have you felt humiliated or emotionally harmed by your partner or ex-partner? (3) Are you now or have you ever been afraid of your partner or ex-partner? (4) Have you ever been physically threatened or hurt by your partner or ex-partner? (5) Have you been forced to have any kind of sexual activity by your partner or ex-partner? (6) Has your partner or ex-partner ever tried to control your behavior; for example, control where you go or whom you see?

The clinician should acknowledge the complexity of intimate partner violence and respect the patient's individual concerns and decisions. The assessment should include an evaluation of safety; the patient should be asked if it is safe for her (or him or any children) to return home. The following are examples of safety considerations: (1) Has the frequency or severity of the violence increased? (2) Is the partner or ex-partner obsessed with the patient? (3) How safe does she (he) feel? (4) Does the partner or ex-partner have a weapon or access to one? (5) Has she (he) been threatened with a weapon? Risk factors for domestic homicide include threats of deadly violence and the presence of a firearm in the home.

TREATMENT

Management of the Abused Patient

The care of patients who have suffered intimate partner violence requires compassion, understanding, and expertise[17] (Table 223-2). The initial response of clinicians to the disclosure of intimate partner violence by patients is crucial in gaining trust and is the basis of further management. Intimate partner violence is a highly stigmatized condition, with the added dimension of risk for further harm from breach of confidentiality.

Before questioning, clinicians should understand the problem, including knowing about the available community services and appropriate referral systems; ensure that the clinical environment is supportive, welcoming, and nonthreatening; place brochures and posters in the clinical setting; try to ensure continuity of care; inform abused women about matters of privacy, safety, and confidentiality; be alert to the signs of abuse and raise the matter when indicated; use verbal and nonverbal communication skills to develop trust; and be compassionate, supportive, and respectful toward abused women. When the topic of intimate partner violence is raised, they should be nonjudgmental, compassionate, and caring when questioning about abuse; be confident and comfortable asking about intimate partner violence; not pressure women to disclose abuse because simply raising the topic may be helpful to women; ask about abuse over the course of several interviews because a woman may disclose abuse at a later date; ensure that the environment is private and confidential; and provide time.

TABLE 223-2 SUMMARY OF SELECTED INTIMATE PARTNER VIOLENCE RECOMMENDATIONS FROM THE WORLD HEALTH ORGANIZATION

CATEGORY	RECOMMENDATION	QUALITY OF EVIDENCE	STRENGTH OF RECOMMENDATION
Woman-centered care	Women who disclose any form of violence by an intimate partner (or other family member) should be offered immediate support by clinicians, at a minimum. If clinicians are unable to provide this first-line support, they should ensure that someone else (within their health care setting or another that is easily accessible) is immediately available to do so.	Indirect	Strong
Identification of survivors	Universal screening is not recommended. Ask about exposure to IPV when assessing conditions that may be caused or complicated by abuse. Written information about IPV should be available in all health care settings.	Low-moderate Indirect No relevant evidence	Conditional Strong Conditional
Care for survivors	Women with preexisting diagnosed or IPV-related mental disorders should receive mental health care delivered by health care professionals with a good understanding of violence against women.	Indirect	Strong
	Cognitive-behavioral therapy or eye movement desensitization and reprocessing interventions, delivered by health care professionals with a good understanding of violence against women, should be offered to women with post-traumatic stress disorder who are no longer experiencing violence.	Low-moderate	Strong
	Women who have spent at least 1 night in a shelter, refuge, or safe house should be offered a structured program of advocacy, support, and/or empowerment.	Low	Conditional
	Pregnant women should be offered brief- to medium-duration empowerment counseling (by counselors with specific training about IPV) and IPV advocacy/support, including a safety component.	Low	Conditional
	For children exposed to IPV at home, a psychotherapeutic intervention should be offered.	Moderate	Conditional
Training of clinicians	Training at a prequalification level in first-line support for women who have experienced IPV should be given to clinicians (in particular, physicians, nurses, and midwives).	Very low	Strong
	Clinicians offering care to women should receive in-service training integrated with training on managing sexual assault.	Low-moderate	Strong
Health care policy	Care for women experiencing IPV should be integrated into existing health services rather than as a stand-alone service.	Very low	Strong
Mandatory reporting	Mandatory reporting to the police by clinicians is not recommended; clinicians should offer to report the incident to the appropriate authorities (including the police) if the woman wants this and is aware of her rights.	Very low	Strong

IPV = intimate partner violence.

Reproduced from Feder G, Wathen CN, MacMillan HL. An evidence-based response to intimate partner violence: WHO guidelines. *JAMA*. 2013;310:479-480.

The immediate response to disclosure should be nonjudgmental, with compassion, support, and conveying belief of experiences. The clinician should acknowledge the complexity of the problem and respect the woman's unique concerns and decisions, prioritize the needs identified by the woman, help ensure that social and psychological needs are met, take time to listen, validate her experiences, provide information and encouragement, respond to any concerns about safety, and offer referrals to specialist help. The response in later interactions should be patient and supportive, with emotional connection through kindness, care, recognition, understanding, and advocacy. The clinician should allow the victim to progress at her own therapeutic pace; understand the chronicity of the problem and provide follow-up and continued support; respect the woman's wishes and not pressure her into making any decisions; be nonjudgmental if a woman does not follow up with referrals immediately; and give abused women an opportunity to disclose abuse at a later date.

Beyond their initial response and managing the acute physical and mental health sequelae of abuse, most generalists have neither the expertise nor the capacity to meet the specific legal, financial, housing, and safety needs of women who experience intimate partner violence. A key step, particularly in the context of current or recent violence, is to offer referral to an advocacy program and to psychological interventions (individual or group-based). Advocacy programs, which can provide physical and psychosocial benefits,[A2] engage with individual clients who are being abused, aiming to empower them and linking them to community services. Core activities of advocacy include provision of legal, housing, and financial advice; facilitating access to and use of community resources, such as refuges (shelters, safe houses) and emergency housing; and provision of safety planning advice. Advocates can also provide ongoing support and informal counseling.[A2] If such services are not immediately available, shelters and refuges often provide these kinds of services for women both in residences and on an outreach basis. The provision of such advocacy can enable rehousing opportunities that improve mental health and safety.[18]

For women who experience intimate partner violence, psychological therapies probably reduce depression and may reduce anxiety, but they have less certain impacts on post-traumatic stress disorder, re-exposure to intimate partner violence, and safety planning; explicit trauma-informed psychological interventions may be more beneficial.[A3] If women are still in an abusive relationship, psychological therapy must be accompanied by advocacy that prioritizes the safety of the survivor.

Management of the Abusive Patient

Physicians often also interact with male patients who perpetrate intimate partner violence, thereby providing a potential to intervene.[19] If a patient discloses perpetration of intimate partner violence, physicians should assess for lethality, readiness to change, and comorbid medical conditions that could affect treatment, such as substance use disorders and mental illness. Referrals to a qualified therapist or batterer intervention program should be offered, but requirement to disclose intimate partner violence is dependent on local jurisdictions.

The detailed assessment and treatment of the abuser should be conducted by expert professionals. To date there is insufficient evidence to recommend specific treatment for those committing intimate partner violence. Behavioral interventions have been disappointing, with generally little or no benefit or potential harm (i.e., increased recidivism), but cognitive-behavioral interventions with an emphasis on gender relations may be effective in reducing violence.[A4] For perpetrators who have alcohol or substance misuse, interventions specifically for misuse are of uncertain benefit.[A5,A6]

Couples Therapy

Couples therapy is probably not appropriate or safe when intimate partner violence is present in a relationship, but it can reduce further violence in couples in which the man had not been violent in the past 6 months.[A7] If abusers are enrolled in treatment programs, women must be provided with concurrent advocacy and support.

Health Care Providers

With intimate partner violence now clearly identified as a health problem, all providers who encounter patients who may be exposed to intimate partner violence should be able to recognize the problem and initiate intervention. Training can improve knowledge and attitudes vis-à-vis intimate partner violence, as well as identification and referral rates[20] but without evidence for a sustained effect or improved patient outcomes.[A8]

PREVENTION

From a public health perspective, primary prevention of intimate partner violence is a priority. However most of the available research from economically developed countries focuses on the health care response to the survivors of intimate partner violence, both while a woman is still exposed to abuse (secondary prevention) and when she is experiencing the long-term health problems associated with intimate partner violence (tertiary prevention).

Efforts aimed at primary prevention of intimate partner violence through educational programs have generally focused on changes in attitude, knowledge, skills, or self-reports of dating (relationship) violence. Although data are limited for physical or emotional health outcomes, programs to prevent adolescent dating violence appear to have at least short-term benefits.[A9]

There is no clinical trial evidence for the effectiveness of interventions in general medical settings to prevent intimate partner violence against pregnant women. For secondary prevention, effective advocacy should include education and information on abuse, rights and resources, active referral and liaising with other services, and risk assessment and safety planning.[A10] Access to social support through the use of advocates with strong linkages with community-based structures and networks can improve mental health outcomes for survivors of intimate partner violence.[A11]

PROGNOSIS

The prognosis of intimate partner violence with and without intervention is uncertain. In a U.S. cohort study, 37% of participants were still being abused after 3.5 years. In one 3-year follow-up of participants who received an advocacy intervention after leaving a shelter, 36% had been assaulted by their original partner or a new partner in the 6 months before the interview. The difference in re-victimization at 2 years between intervention and control arms did not persist, but there was still a significant difference in quality of life and social support among women receiving advocacy.

In general, women who seek help when they have recently left or are considering leaving an abusive relationship usually have improved quality of life with less depression, post-traumatic stress, and physical symptoms, although improvement tends to plateau within 9 months.[21] The main predictor of improvement in symptoms is social support, whereas the main predictor of no improvement is continued exposure to intimate partner violence.

224 APPROACH TO THE PATIENT WITH METABOLIC BONE DISEASE

THOMAS J. WEBER

DIAGNOSIS

History

Patients with metabolic bone disease may present to the clinician in a number of ways, ranging from no symptoms to disabling musculoskeletal pain, depending on the nature of the underlying disorder. The most common conditions, osteoporosis (Chapter 225) and primary hyperparathyroidism (Chapter 227), encompass a clinical spectrum that ranges from asymptomatic (diagnosed by low bone density and an elevated serum calcium, respectively) to severe disease (fractures and bone pain).[1,2] Less common conditions, such as osteomalacia (Chapter 226), have more predictable presentations. In osteoporosis (Chapter 225), fractures of the long bones (humerus, distal forearm, femur, and tibia) are clearly evident, whereas fractures at other sites (vertebrae, ribs, pelvis) may not be clinically apparent (see later and Chapter 225). Patients with osteomalacia may complain of deep bone pain or aches, although often it is difficult for them to distinguish such pain from muscular pain. They may also report proximal muscle weakness that impairs their ability to ascend stairs. Vitamin D deficiency (Chapter 199), the most common cause of osteomalacia, may confer similar bone and muscle complaints as well. Tumor-induced osteomalacia is a paraneoplastic disorder caused by ectopic secretion of fibroblast growth factor 23 (Chapter 226).[3] In hyperparathyroidism (Chapter 227), either self-reported or elicited fatigue may be a common complaint, along with mildly impaired cognition and memory. A history of recurrent nephrolithiasis is a hallmark of symptomatic primary hyperparathyroidism. Patients with hypophosphatasia typically present with musculoskeletal pain and history of fractures. Finally, it is important to understand many inherited metabolic bone disorders have associated dental-oral-craniofacial manifestations that help distinguish the underlying disorder.

Physical Examination

Patients may exhibit physical clues to their skeletal condition. Height loss of more than 2 inches from a self-reported maximum, measured accurately with a calibrated stadiometer, may suggest the presence of vertebral compression fractures, which are clinically silent in up to three fourths of patients. Corresponding thoracic kyphosis may be present, and tenderness to palpation or percussion over the spinous process may suggest a recent vertebral fracture. Thoracic kyphosis will also impart quantifiable physical characteristics, including decreased rib-to-pelvis (Fig. 224-1) and increased wall-to-occiput distances. The wall-to-occiput distance, which reflects the degree of kyphosis, is the space between the wall and the occiput of the head when a patient stands straight with the heel, buttocks, and back against the wall and with the epicanthal folds and superior margin of the outer ear parallel with the ground. These measurements, which may be followed clinically, predict vertebral fractures. Patients may also exhibit signs of secondary causes of osteoporosis (e.g., blue sclerae with osteogenesis imperfecta [Chapter 239], goiter and proptosis with hyperthyroidism [Chapter 207], facial plethora and purple striae with Cushing syndrome [Chapter 208]). Patients with Paget disease of bone (which is characterized by an increase in bone resorption by abnormal osteoclasts, followed by rapid formation of poorly organized, structurally weak bone; Chapter 228) may have a skeletal deformity and warmth over the affected sites.

Patients with osteomalacia often have tenderness to palpation over the tibia or other long bones owing to expansion of the subperiosteal space by undermineralized osteoid with resultant periosteal nerve irritation. These patients may also have a wide-based, "waddling" gait due to pain.

Hyperparathyroid patients may have flank tenderness if active nephrolithiasis (Chapter 111) is present and can rarely have corneal calcification if hypercalcemia is severe and long-standing. Such patients rarely have a palpable parathyroid adenoma. If present, however, a diagnosis of parathyroid carcinoma should be entertained.

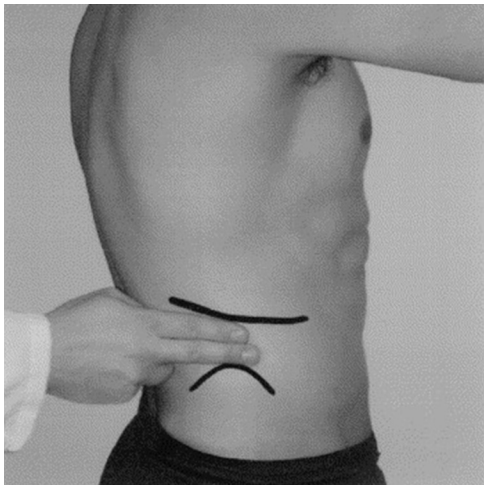

FIGURE 224-1. Method of assessing rib-pelvis distance. While standing behind the subject, the examiner holds his or her hands vertically and places them into the space between the inferior margin of the ribs and the superior surface of the pelvis in the mid-axillary line. The vertical distance is then measured in fingerbreadths.

Laboratory and Radiologic Investigations

Laboratory studies (Table 224-1) are a useful adjunct in the evaluation of metabolic bone disease, although their specificity depends on the disease in question. In some conditions, the diagnosis is reasonably more securely based on abnormal biochemical studies, such as alkaline phosphatase (elevated in Paget disease [Chapter 228] and depressed in hypophosphatasia [Chapter 226]), serum phosphorus (abnormal in disorders of fibroblast growth factor 23 metabolism), and parathyroid hormone (elevated in hyperparathyroidism). In other situations, studies for the evaluation of osteoporosis are generally not specifically diagnostic, but rather are supportive of secondary causes that may contribute to bone loss; examples include levels of thyroid-stimulating hormone, 25(OH)D, and testosterone. Additional investigations may also be required as clinically indicated, especially in individuals who have a markedly lower bone density than expected for age (see later and Chapter 225).[4] More sophisticated studies that target a specific diagnosis should be based on the history and examination (e.g., genetic testing for hypophosphatasia or osteogenesis imperfecta). Bone turnover markers, which are cellular products of bone formation and resorption that can be measured in the blood and urine of patients, may provide noninvasive information on skeletal turnover (i.e., high or low) but cannot be used for diagnosis and have not been proven to be useful for monitoring patients with metabolic bone disease.

Radiologic studies are critical to the diagnosis and management of metabolic bone disease. Most widely used and critical to management of osteoporosis is bone mineral density (BMD) testing, generally by dual energy x-ray absorptiometry (DXA; see Chapter 225). DXA, which is a low-radiation, noninvasive examination of the spine, proximal femur, and distal forearm, may be used to make serial assessments of the likelihood of future fracture and to identify and subsequently follow the treatment response to pharmacologic or conservative therapies.

Because the most common clinical event is fracture, plain radiographs of the involved skeletal sites are often indicated. However, plain radiographs are relatively insensitive in identifying stress fractures and may also lag behind a frank fracture by hours or days. As a result, additional, more sensitive modalities, including computed tomography (CT) and magnetic resonance imaging (MRI), may be preferred in these circumstances to confirm a fracture. CT and MRI can reveal characteristic patterns of skeletal involvement in certain conditions (e.g., Paget disease often involves the skull, pelvis, proximal femur, or

Thyroid-stimulating hormone	24-Hour urine cortisol
24-Hour urine calcium and creatinine	Celiac panel (antigliadin/anti-endomysial antibodies)
Serum 25(OH)D	Fasting morning testosterone (men)

SPEP = serum protein electrophoresis; UPEP = urine protein electrophoresis.

ABSTRACT

Metabolic bone disease encompasses both common (e.g., osteoporosis) and more rare (e.g., X-linked hypophosphatemic rickets) conditions that may be clinically silent or present with fractures and bone pain. Diagnostic assessment of metabolic bone disease includes laboratory and radiographic studies that, although not absolutely specific, help guide evaluation and management of bone disorders. Treatments of metabolic bone disease often have common components (e.g., calcium, vitamin D, bisphosphonates) but may also include disease-specific therapy (e.g., enzyme replacement for hypophosphatasia).

tibia). Whole body bone scintigraphy with the radioisotope techneticum-99m is the most sensitive tool to identify an active skeletal process but is nonspecific as to the nature of the underlying process (e.g., fracture, infection, malignancy).

Finally, although rarely needed, tetracycline-labeled, transcortical bone biopsy of the iliac crest, with subsequent histomorphometric analysis, may be useful in the management of patients. Bone biopsy, which is generally performed by an orthopedic surgeon under conscious sedation, may be indicated to guide management in patients with excessive bone fragility that cannot be adequately characterized by noninvasive means (e.g., patients who have renal osteodystrophy [Chapter 116], suspected osteomalacia, or fractures with normal bone mineral density by DXA).

TREATMENT

Management of patients with metabolic bone disease is generally directed by the disease process, although there are some unifying aspects of treatment. Adequate intake of calcium and vitamin D, usually through a combination of diet and supplements, is recommended for patients with osteoporosis (Chapter 225). High-dose vitamin D is indicated for low-vitamin D–related osteomalacia (Chapter 226). Phosphorus in combination with vitamin D analogues (i.e., calcitriol) has been used traditionally to heal osteomalacia and facilitate normal longitudinal growth in children and adolescents and to promote mineralization and heal stress fractures in adults with certain osteomalacic conditions (e.g., X-linked hypophosphatemic rickets and tumor-induced osteomalacia). Weight bearing and resistive exercise are also advisable for osteoporotic patients,[5] although physical therapy consultation may be indicated in patients at high risk for fracture (previous fractures, frequent falls).

Pharmacotherapy with oral and parenteral bisphosphonates is frontline therapy for patients with both osteoporosis (Chapter 225) and Paget disease (Chapter 228)[6] because of the anticatabolic effect on excessive osteoclastic bone resorption that underlies these diseases. In addition, other antiresorptive drugs, such as raloxifene and denosumab, are approved for the treatment of osteoporosis.[7] Parenteral bisphosphonates and denosumab also are effective in combating malignancy-related bone disease (e.g., metastatic breast cancer, multiple myeloma). Finally, the anabolic bone agents teriparatide and abaloparatide, which are recombinant parathyroid hormone and parathyroid hormone–related peptide analogues, respectively, are useful in "building" bone density and reducing the risk of fracture in patients who have severe osteoporosis, defined as very low bone mineral density, high fracture risk, and/or history of multiple fractures. Medications such as the monoclonal anti-sclerostin antibody romosozumab also can target the Wnt pathway, which is critical for bone formation.[8] Burosumab, which is a skeletal-specific monoclonal antibody against the hypophosphatemia-inducing factor fibroblast growth factor 23 (FGF-23), can be useful for the treatment of X-linked hypophosphatemia (Chapter 226).

225 OSTEOPOROSIS

THOMAS J. WEBER

DEFINITION

Osteoporosis is defined as a skeletal disorder that is characterized by compromised bone strength and that predisposes to an increased risk for fracture. The pertinent clinical outcomes of this disease include fractures, bone pain, loss of height, and physical deformity. The concept of bone strength is central to understanding the disorder because patients who suffer an osteoporotic or fragility fracture may or may not have osteoporosis by bone mineral density criteria. The World Health Organization defines *osteoporosis* as a bone mineral density that is equal to or greater than 2.5 standard deviations below that of an average individual at peak bone mass (generally ages 20 to 30 years, depending on the measured skeletal site). Osteopenia, or low bone density, is defined as a bone mineral density between −1.1 and −2.4 standard deviations, inclusive, below young average normal.

EPIDEMIOLOGY

Approximately half of White women will develop an osteoporosis-related fracture in their lifetime, which is greater than their risk for breast cancer, heart attack, and stroke combined. In addition, one in five men will also have an osteoporosis-related fracture. Nearly three fourths of these fractures occur in women, with most occurring in White women.

The rate of osteoporotic fractures varies significantly across ethnicities and geography. Blacks have a lower lifetime risk for osteoporotic fracture, approximately half that of Whites. Differences in bone size, bone microarchitecture (thicker trabeculae in Blacks), body composition, calcium absorption in youth, and life expectancy are potential reasons for this phenomenon. Asian Americans and Hispanics have risks of fracture that are intermediate between that of Whites and Blacks, even though Asian Americans have bone mineral densities that generally approximates that of Whites. Indeed, the risk for hip fracture in U.S. Asian men and women is actually equal to or lower than that of U.S. Blacks. These U.S. data are consistent with the global experience as well, because rates of hip fracture in China are lower than those observed in the United States, despite similar bone density at the hip. Differences in hip geometry, physical activity, and diet have been proposed as possible explanations. For unknown reasons, however, rates of hip fracture have actually been increasing in the Far East, whereas they have declined somewhat in the United States. Changing patterns of nutrition and physical activity could be responsible for the former, although the latter observation remains heretofore unexplained.

The most common site of osteoporotic fracture is the spine, which accounts for more than 750,000 fractures annually. Fractures of the proximal femur, which disproportionately confer a greater cost than other osteoporotic fractures, account for approximately 300,000 fractures annually in the United States and nearly 75% of the costs. Additional sites of fracture include the distal forearm, proximal humerus, and pelvis, with the latter two more commonly occurring in elderly people.

The risk for fracture increases markedly with age,[1] although the pattern of fracture risk differs by skeletal site. The risk for Colles fractures increases until the mid-60s and then plateaus, whereas the risk for hip fractures increases exponentially in woman after the age of 65 years. The risk of vertebral fracture rises earlier than that of hip, but many spine fractures are not clinically apparent and are identified only by radiographic assessment. Although clinically silent, such fractures confer a significant independent risk for future fractures, particularly if they are recent.

Men also have an age-independent increase in the risk of fracture, although the increase in incidence generally lags at least 5 to 10 years behind that of women (Fig 225-1). This sex-based difference in the incidence of fracture is likely related to anatomic differences. Specifically, although men and woman have similar volumetric bone density at a given skeletal site, men's larger bone size confers an independent mechanical protection against fracture.

The aging of the U.S. population and the independent contribution of age to the risk of fracture predict that the morbidity and cost related to osteoporosis will increase in the United States alone to greater than 3.2 million fractures, with an associated annual cost of $95 billion by the year 2040. Despite these ominous predictions, less than one third of women who incur a low-trauma hip fracture typically undergo bone density measurement or initiate pharmacologic antifracture therapy, thereby underscoring the need for significant improvement in the delivery of osteoporosis care.

PATHOBIOLOGY

Normal Bone Biology

Bone mineral density in adults is determined by the magnitude of bone acquisition during adolescence and young adulthood compared with the rate of bone loss that ensues thereafter. These processes are generally referred to as bone modeling and remodeling, respectively. Heritable factors, including sex and ethnicity, account for 60 to 80% of the variability in skeletal development, including peak bone mass, bone size, and bone geometry, although nutrition, lifestyle, and other factors also have a significant impact. Peak bone mass is achieved in most individuals by the early to late 20s and differs in timing by skeletal site (ages 18 to 20 years for proximal femur, 25 to 30 years for spine). Modeling of the skeleton during this time represents a true increase in bone mass and bone size through endochondral ossification of the axial skeleton and periosteal apposition of the appendicular skeleton.

Skeletal remodeling is a finely orchestrated process of bone resorption and subsequent formation. It is a necessary physiologic function that results in repair of damaged bone and redistribution of the skeleton to adapt to changes in mechanical stress and to provide calcium to the systemic circulation for critical

225 OSTEOPOROSIS

THOMAS J. WEBER

DEFINITION

Osteoporosis is defined as a skeletal disorder that is characterized by compromised bone strength and that predisposes to an increased risk for fracture. The pertinent clinical outcomes of this disease include fractures, bone pain, loss of height, and physical deformity. The concept of bone strength is central to understanding the disorder because patients who suffer an osteoporotic or fragility fracture may or may not have osteoporosis by bone mineral density criteria. The World Health Organization defines *osteoporosis* as a bone mineral density that is equal to or greater than 2.5 standard deviations below that of an average individual at peak bone mass (generally ages 20 to 30 years, depending on the measured skeletal site). Osteopenia, or low bone density, is defined as a bone mineral density between −1.1 and −2.4 standard deviations, inclusive, below young average normal.

EPIDEMIOLOGY

Approximately half of White women will develop an osteoporosis-related fracture in their lifetime, which is greater than their risk for breast cancer, heart attack, and stroke combined. In addition, one in five men will also have an osteoporosis-related fracture. Nearly three fourths of these fractures occur in women, with most occurring in White women.

The rate of osteoporotic fractures varies significantly across ethnicities and geography. Blacks have a lower lifetime risk for osteoporotic fracture, approximately half that of Whites. Differences in bone size, bone microarchitecture (thicker trabeculae in Blacks), body composition, calcium absorption in youth, and life expectancy are potential reasons for this phenomenon. Asian Americans and Hispanics have risks of fracture that are intermediate between that of Whites and Blacks, even though Asian Americans have bone mineral densities that generally approximates that of Whites. Indeed, the risk for hip fracture in U.S. Asian men and women is actually equal to or lower than that of U.S. Blacks. These U.S. data are consistent with the global experience as well, because rates of hip fracture in China are lower than those observed in the United States, despite similar bone density at the hip. Differences in hip geometry, physical activity, and diet have been proposed as possible explanations. For unknown reasons, however, rates of hip fracture have actually been increasing in the Far East, whereas they have declined somewhat in the United States. Changing patterns of nutrition and physical activity could be responsible for the former, although the latter observation remains heretofore unexplained.

The most common site of osteoporotic fracture is the spine, which accounts for more than 750,000 fractures annually. Fractures of the proximal femur, which disproportionately confer a greater cost than other osteoporotic fractures, account for approximately 300,000 fractures annually in the United States and nearly 75% of the costs. Additional sites of fracture include the distal forearm, proximal humerus, and pelvis, with the latter two more commonly occurring in elderly people.

The risk for fracture increases markedly with age,[1] although the pattern of fracture risk differs by skeletal site. The risk for Colles fractures increases until the mid-60s and then plateaus, whereas the risk for hip fractures increases exponentially in woman after the age of 65 years. The risk of vertebral fracture rises earlier than that of hip, but many spine fractures are not clinically apparent and are identified only by radiographic assessment. Although clinically silent, such fractures confer a significant independent risk for future fractures, particularly if they are recent.

Men also have an age-independent increase in the risk of fracture, although the increase in incidence generally lags at least 5 to 10 years behind that of women (Fig 225-1). This sex-based difference in the incidence of fracture is likely related to anatomic differences. Specifically, although men and woman have similar volumetric bone density at a given skeletal site, men's larger bone size confers an independent mechanical protection against fracture.

The aging of the U.S. population and the independent contribution of age to the risk of fracture predict that the morbidity and cost related to osteoporosis will increase in the United States alone to greater than 3.2 million fractures, with an associated annual cost of $95 billion by the year 2040. Despite these ominous predictions, less than one third of women who incur a low-trauma hip fracture typically undergo bone density measurement or initiate pharmacologic antifracture therapy, thereby underscoring the need for significant improvement in the delivery of osteoporosis care.

PATHOBIOLOGY

Normal Bone Biology

Bone mineral density in adults is determined by the magnitude of bone acquisition during adolescence and young adulthood compared with the rate of bone loss that ensues thereafter. These processes are generally referred to as bone modeling and remodeling, respectively. Heritable factors, including sex and ethnicity, account for 60 to 80% of the variability in skeletal development, including peak bone mass, bone size, and bone geometry, although nutrition, lifestyle, and other factors also have a significant impact. Peak bone mass is achieved in most individuals by the early to late 20s and differs in timing by skeletal site (ages 18 to 20 years for proximal femur, 25 to 30 years for spine). Modeling of the skeleton during this time represents a true increase in bone mass and bone size through endochondral ossification of the axial skeleton and periosteal apposition of the appendicular skeleton.

Skeletal remodeling is a finely orchestrated process of bone resorption and subsequent formation. It is a necessary physiologic function that results in repair of damaged bone and redistribution of the skeleton to adapt to changes in mechanical stress and to provide calcium to the systemic circulation for critical

ABSTRACT

Osteoporosis, which is a skeletal disorder characterized by compromised bone strength, predisposes an individual to an increased risk for fracture and accounts for almost 2 million fractures occurring annually in the United States at an estimated cost of $57 billion. Osteoporosis is most prevalent in older postmenopausal women, but it also affects men and individuals with risk factors for bone loss. It is identifiable clinically (low trauma fractures) and by testing (dual energy x-ray absorptiometry). Treatment with a number of medications approved by the U.S. Food and Drug Administration can significantly reduce the risk for low-trauma fractures.

cellular processes. The osteocyte, which accounts for 90 to 95% of all bone cells, is the critical cell that regulates both resorption and formation. Osteocytes are derived from osteoblasts that are embedded within the bone matrix. During this maturation phase, this "osteoid-osteocyte" cell actively secretes and calcifies bone matrix material. In addition, mature osteocytes within bone contain dendritic processes that may directly regulate the recruitment of osteoblasts and formation of the bone. The protein sclerostin, which directly downregulates bone formation through the Wnt pathway, is an important part of this process. Mature osteocytes also may form new bone within their lacunae. In addition, osteocytes produce proteins that regulate mineralization, including positive (PHEX, DMP-1) and negative (FGF-23) factors.

Osteocytes also regulate bone resorption, both directly through apoptosis proximate to skeletal microcracks or fatigue damage in need of repair as well as indirectly through enhancement of pre-osteoblast or mesenchymal stromal cell development. These events result in the production, expression, and release of cytokines that are critical to the recruitment and development of osteoclasts, including interleukin-1 (IL-1), IL-6, osteoprotegerin (OPG), and receptor activator of nuclear factor-κB ligand (RANKL). The cognate receptor for RANKL, RANK, is expressed on the surface of the developing and mature osteoclast, which itself is a derivative of cells of the monocyte-macrophage lineage. RANKL is a critical determinant of osteoclast recruitment, development, and survival, such that disruption of RANKL signaling results in high bone density fragility disorders (e.g., osteopetrosis). OPG, which is also produced by pre-osteoblasts, is a decoy receptor for RANK and binds to RANKL, thereby preventing RANKL binding to RANK serving as an endogenous suppressor of osteoclast function. In essence, RANKL/OPG represent a "yin/yang" paradigm, in which osteoclast biology and bone resorption are intricately regulated and controlled (E-Fig. 225-1).

Factors Affecting Peak Bone Mass and Remodeling

Peak bone mass is achieved by the third decade. Longitudinal studies in children and adolescents suggest that hormonal, physical activity, nutritional, and genetic factors are important in this process. Hereditary influence is the most important determinant and least well understood. Growth hormone and sex hormones play critical roles in growth of the appendicular (long bones) and axial (vertebrae) skeleton, with the former maturing earlier than the latter (end of puberty vs. young adulthood). Males have larger bones as a result of greater periosteal (outer surface of bone) expansion of bone than occurs in females. Current evidence supports a positive effect of exercise and loading on bone size and mineral density, although a subsequent potential antifracture benefit later in adult life is not proven. Poor nutrition and concomitant disease may also affect bone accrual, primarily by delaying the onset and progression of puberty, although "catch-up" growth, which depends on the degree of insult and timing of resolution, also can occur.

Although these factors are all important, genetic factors appear to account for 60 to 80% of the variance in peak bone mineral density. Genome-wide association studies have identified 90 distinct loci that are significantly associated with bone mineral density. Additionally, the genetic determination of bone mineral density is relatively skeletal site-specific (E-Fig. 225-2). Three obligatory pathways of bone metabolism were initially identified by genome-wide association studies, (i.e., Wnt, RANK-RANKL-OPG, and endochondral ossification), and two additionally pathways (NOTCH and Indian Hedgehog) have also recently been identified, although they may interact through the Wnt pathway.[2] Wnt signaling pathway is obligatory for bone formation, owing to its role in the proliferation and differentiation of osteoblasts. Endochondral ossification, a process that involves the cartilage growth plate and subsequent ossification of the cartilaginous skeleton, is dependent on transcription factors (SOX6, RUNX2) and proteins (parathyroid hormone–related peptide, bone sialoprotein 2, and osteopontin) that are necessary for the development of the cartilage growth plate, for bone matrix mineralization, and for osteoblast differentiation. These three initially identified pathways are now the target of existing and developing therapies for osteoporosis.

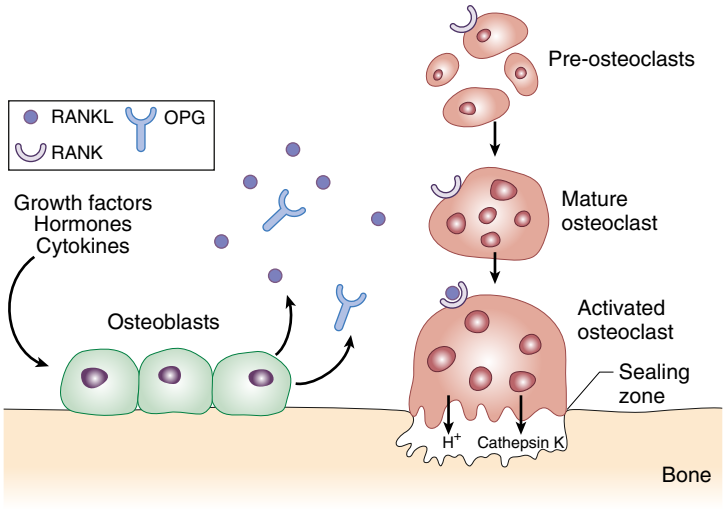
In adults, bone remodeling is a physiologic process through which skeletal repair and adaption to changes in biomechanical stress occur. The bone remodeling cycle occurs in the basic multicellular unit, which itself is composed of bone-resorbing osteoclasts, bone-forming osteoblasts, bone lining cells, and embedded osteocytes and is the apparatus that facilitates remodeling (E-Fig. 225-3). After the age of 30 years, this process is reasonably matched, thereby resulting in rates of bone loss of only 0.3 to 0.5% per year from the third through fifth decades of life. As individuals age, mismatches in bone remodeling (as a result of reduced formation, increased resorption, or a combination of both) result in greater rates of bone loss. Biologic changes, such as menopause (Chapter 222) and aging, systemic disease, personal vices, and medications (most notably glucocorticoids), may contribute to this imbalance. In addition, genetic factors influence the rates of bone loss and fracture.[3]

Mechanisms of Bone Loss

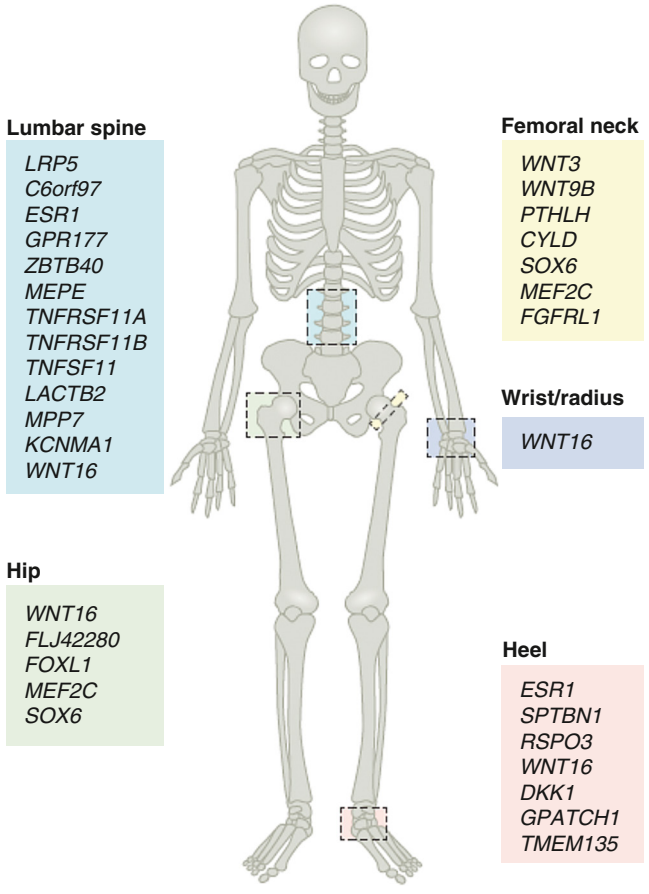
"Natural" and Aging-Related Bone Loss

The rate of net bone loss accelerates during the latter decades of life because of a number of factors. Perhaps most important for women, rates of bone loss increase substantially in the perimenopausal and early postmenopausal years (Chapter 222), amounting to losses of 1 to 5% per year. Unfortunately, no biologic markers currently can determine which women a priori are "rapid losers." Bone loss is slower in obese women, likely because of higher estrogen levels afforded by production through aromatization in adipose tissue. Following both natural and surgical menopause, a decline in circulating estrogen is primarily responsible for bone loss, which is mediated primarily through upregulation of cytokines (most notably RANKL) and a resultant increase in the number, activity, and depth of osteoclast-mediated bone resorption sites. In addition, the production of osteoprotegerin is diminished, thereby further amplifying bone resorption, although estrogen replacement can restore the production of osteoprotegerin while reducing RANKL expression and thereby help mitigate bone loss during this period. Although bone resorption and formation occur sequentially during this period, resorption outpaces formation because of potentiation of the former aided by the release of soluble cytokines, thereby resulting in a significant uncoupling of bone remodeling and accelerated bone loss. Fortunately, this phase of rapid bone loss is typically limited to 2 to 3 years in most women.

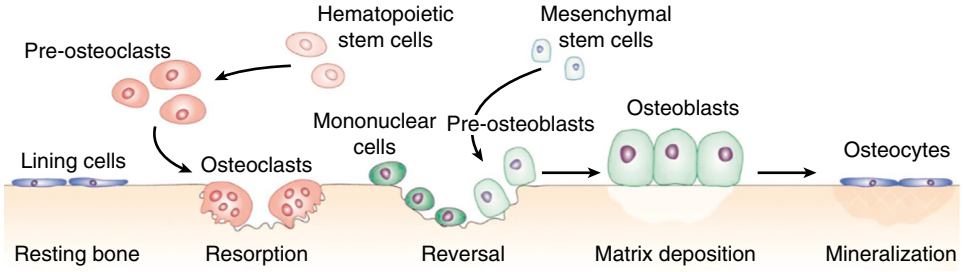
Evidence also supports a key role for reduced estrogen levels in men, perhaps because reduced aromatase activity in fat tissue leads to loss of bone and an increased risk of fracture.[4] With aging, declines in circulating insulin-like growth factor-I levels also may inhibit the production of mesenchymal stromal



E-FIGURE 225-1. RANKL expressed by osteoblast lineage cells binds to RANK on the surface of pre-osteoclasts and mature osteoclasts, resulting in increased bone resorption through an increase in osteoclast differentiation, activity, and survival. Osteoprotegerin (OPG) is a "decoy receptor," also produced by osteoblasts, that binds to RANKL, preventing RANKL binding to RANK and thereby inhibiting osteoclastic bone resorption. It is the balance of RANKL and OPG that determines the ultimate rate of bone resorption. (Adapted from Lewiecki EM. New targets for intervention in the treatment of postmenopausal osteoporosis. *Nat Rev Rheumatol*. 2011;7:631-638.)



E-FIGURE 225-2. The most important genes linked to bone mineral density (BMD) variation. These are the key genes identified to date in various genome-wide association studies for BMD at various skeletal sites: the lumbar spine, hip, wrist or radius, heel, and femoral neck. (From Karasik D, Rivadeneira F, Johnson ML. The genetics of bone mass and susceptibility to bone diseases. *Nat Rev Rheumatol*. 2016;12:323-334.)



E-FIGURE 225-3. The basic multicellular unit (BMU) moving across the bone tissue. First, 10 to 20 osteoclasts resorb old or damaged tissue; then they recruit 1000 to 2000 osteoblasts, which produce new bone matrix. The BMU moves at a speed of 20 to 40 μm/day and survives for up to 6 months. (From Kapinas K, Delany AM. MicroRNA biogenesis and regulation of bone remodelling. *Arthritis Res Ther*. 2011;13:220.)

cells and pre-osteoblasts, in addition to limiting periosteal bone expansion. Bone loss in later decades also is caused by lower 25-hydroxyvitamin D (25[OH]D) levels, often related to restricted sun exposure and a reduced capacity to generate previtamin D in the skin with aging, as well as limited dietary intake of vitamin D and calcium. Low vitamin D results in secondary hyperparathyroidism (Chapter 227), which accelerates cortical bone loss, as well as likely increasing the risk for falls. Increase in bone marrow adiposity is also inversely and significantly correlated with aging-related bone loss, in part because fewer osteoblast precursors are formed. Finally, loss of weight and muscle mass (sarcopenia) is associated with bone loss, with evidence suggesting that a common factor (myostatin) may provide insights on this muscle-bone interaction.

Secondary Causes and Clinical Impact of Bone Loss

Bone loss also occurs as a result of secondary processes, such as diseases and medications (see Table 225-1), which can be identified in more than one fourth of individuals with osteoporosis. Endocrine disorders, including hypogonadism (Chapters 216 and 217) and Cushing syndrome (Chapter 208), predominate, but malabsorption (Chapter 126), chronic liver disease (Chapter 139), and certain medications (e.g., antiepileptic drugs such as phenytoin) are also implicated. Glucocorticoids, whether via exogenous administration or endogenous overproduction,[5] reduce bone formation by reducing the function and survival of osteoblasts and osteocytes. Rarely, malignancies can be the principal cause of osteoporosis, with the best example being multiple myeloma (Chapter 173), which causes bone loss through uncoupling of bone resorption and formation. Anorexia nervosa (Chapter 200) interferes with the anabolic effect of insulin-like growth factor-I on bone. Alcohol intake (Chapter 364) of only 1 or 2 drinks per day increases the risk for osteoporosis,[6] likely through suppression of osteoblast function, both directly and indirectly through associated malnutrition, as well as possibly through hypogonadism-associated bone loss from accelerated bone turnover. Tobacco use (Chapter 363) may also accelerate bone loss, owing to global effects that include reduced sex hormones, altered calcium metabolism, and weight loss and frailty, resulting in uncoupled bone remodeling. Finally, relatively rare connective tissue disorders, such as osteogenesis imperfecta (Chapter 229) and Marfan syndrome (Chapter 239), increase skeletal fragility by disturbing the skeletal matrix and mechanical integrity rather than altered bone remodeling.

The age at which bone loss occurs (e.g., young adult vs. an 80-year-old) affects the ability to recover bone mineral density with resolution or treatment of the condition (younger people have more robust recovery than elderly people) and also appears to hold for conditions of accelerated bone resorption (e.g., immobilization) or reduced bone formation (e.g., glucocorticoids). Predicated on and paralleling this observation, the response of bone mineral density to treatment is generally more pronounced in individuals with higher rates of bone turnover, likely reflecting to some extent a "filling in" of bone remodeling space. Menopausal stage in women also influences the rate of bone loss, with greater rates of decline occurring within the first 2 to 3 years of cessation of menses (Chapter 222). A faster rate of bone mineral density decline in the lumbar spine in early menopause also predicts a higher risk of fracture.[7] Concomitant vitamin D deficiency and resulting secondary hyperparathyroidism also potentiate rates of bone loss, particularly in elderly people.

TABLE 225-1 SECONDARY CAUSES OF OSTEOPOROSIS

ENDOCRINE DISORDERS
Hypogonadism: female and male
Hypercortisolism: endogenous and exogenous
Hyperthyroidism
Hyperparathyroidism
Idiopathic hypercalciuria
Diabetes mellitus: type 1 and type 2
NUTRITIONAL AND GASTROINTESTINAL DISORDERS
Malabsorption: celiac disease, gastrointestinal bypass
Vitamin D deficiency
Cirrhosis (including primary biliary cirrhosis)
Pancreatic insufficiency
Inflammatory bowel disease
Cystic fibrosis
Anorexia nervosa, bulimia
HEMATOLOGIC AND ONCOLOGIC DISORDERS
Multiple myeloma
Hemolytic anemia
Hemoglobinopathies: thalassemia, sickle cell

Fragility Fractures

Most fragility fractures, which are defined as fractures occurring from the energy imparted from a fall from a standing height or less, occur in individuals who have low (osteopenia) or even normal bone mineral density. Given these observations, it is clear that other factors (e.g., falls and traumatic injuries) must also significantly influence the risk of fracture. Excluding falls and trauma, however, studies to date have also identified qualitative factors that are integral to bone strength, including skeletal microarchitecture, bone turnover, the accumulation of damage (e.g., microfractures), and the pattern or degree of mineralization. Newer technologies (including high-resolution peripheral quantitative computed tomography and high-resolution magnetic resonance imaging [MRI]) may improve the understanding of how these qualitative changes in bone compromise skeletal strength (Fig. 225-2).[8]

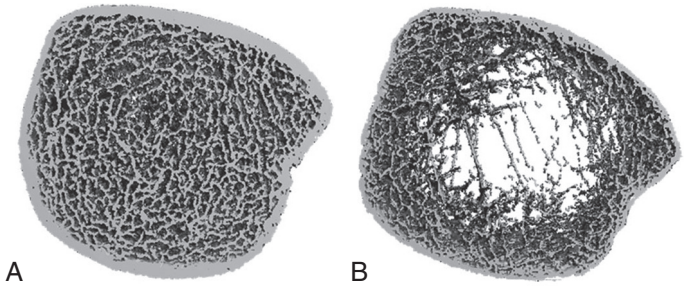

FIGURE 225-2. High-resolution peripheral computed tomography (Xtreme CT) of distal tibia in subject with normal bone mineral density (A) and severe osteoporosis (B). The deterioration in trabecular architecture with reduced trabecular number, trabecular thinning, increased trabecular spacing, generalized cortical thinning, and increased cortical porosity is readily appreciable in the osteoporotic subject. (From Griffith JF, Genant HK. New advances in imaging osteoporosis and its complications. *Endocrine*. 2012;42:39-51.)

CLINICAL MANIFESTATIONS

Low bone mass in and of itself does not cause pain, unless it is due to osteomalacia (Chapter 226). Because osteoporosis typically antedates clinical symptoms by many years, most osteoporotic individuals are asymptomatic.

Osteoporosis may be diagnosed in an individual who presents with a fragility fracture, typically of the vertebrae, proximal femur, proximal humerus, or distal forearm. Other sites that are subject to fragility fractures include the pelvis, ribs, and proximal tibia. Nevertheless, even a high-trauma fracture in a postmenopausal woman or elderly man should cause suspicion for osteoporosis.

Fractures of the spine, which are often asymptomatic, are generally from the midthoracic region through the lower lumbar region, with the greatest frequency at T11 through L2. Patients often present after a fall or a spinal flexion-loading event, in which they may hear a "pop" and complain of sharp midline back pain that may radiate to the flanks. Patients may also present with complaints of back "tiredness," which is improved with sitting or lying down; this symptom is likely related to paraspinal weakness or spasm from abnormal spinal curvature that occurs with chronic vertebral compression. Back pain may commonly be related to other pathology (Chapter 369), such as degenerative disc and spine disease that is concomitantly present.

Vertebral fractures often occur without an obvious acute precipitant. In contrast, nonvertebral fracture events are always clinically evident. Hip fractures generally occur with falls, although they may rarely occur with limited force such as twisting.

Physical Examination

Physical examination may indicate the presence of osteoporosis and associated fractures, as well as potentially identifying underlying secondary processes contributing to the disease. Measured height loss, best confirmed using a calibrated device such as a stadiometer, of greater than 4 cm since young adult maximum height is suggestive of prior vertebral fractures. Height loss also occurs with scoliosis and aging (approximately ⅓ inch of height is lost per decade after age 50 years). A kyphotic deformity (Chapter 86) of the upper thoracic spine may be present, although it is important to distinguish it from accentuated cervical lordosis with associated prominence of T1. Spinal tenderness to palpation and percussion can occur with an acute vertebral compression fracture. Palpable tenderness of the long bones may suggest underlying osteomalacia (Chapter 226) with periosteal expansion and nerve irritation. Reduced rib-pelvis and increased wall-occiput distances (<2 and >0 fingerbreadths, respectively) also are correlated with vertebral fractures as well.

DIAGNOSIS

In symptomatic patients, the diagnosis of osteoporosis is commonly made by radiographs of the involved site. Radiologic findings also may identify the presence of osteoporosis, serendipitously when obtained for other reasons in asymptomatic patients with osteoporosis.

Plain films can detect bone loss by means of accentuation of vertical striations on spine radiographs that represent loss of horizontal trabeculae, although this generally indicates bone density loss of at least 25% or more. Kyphosis and compression fractures may be present, and patients often are unaware of the deformities because nearly three fourths of such fractures occur without acute pain. Lateral chest radiographs and computed tomographic (CT) scans often identify such fractures (Fig. 225-3). The degree of compression fracture is also important because more severe fractures (>25% vertebral height loss) especially appear to predict future vertebral fractures.

When recent fractures are suspected, CT and MRI may be used, given that plain radiographs have a lower sensitivity acutely and for detecting stress fractures. MRI also can be used to define a vertebral fracture with persistent swelling and edema based on T2 characteristics, thereby potentially identifying patients who could benefit from vertebroplasty or kyphoplasty. Finally, whole-body bone scintigraphy is the most sensitive test for detecting fracture within the past 6 to 12 months but can be falsely positive because of inflammation, infection, or tumor.

Bone Mineral Density Measurement

Most patients with osteoporosis are diagnosed on the basis of a measurement of bone mineral density, generally by dual–energy x-ray absorptiometry (DXA).[9] DXA scanning is a low-radiation–based radiologic measurement of the areal bone density (g/cm) of the lumbar spine, proximal femur, and distal radius. Osteoporosis can be diagnosed if the bone mineral density of a postmenopausal woman or man older than age 50 years is more than 2.5 standard deviations below young average normal individuals (T score ≤−2.5). A T score between −1.0 and −2.5 is considered low bone density, or osteopenia, and a Z score (age-matched bone mineral density) in premenopausal women and men younger than 50 years that is more than 2 standard deviations below that of an average age-matched individual is considered low bone density for age.

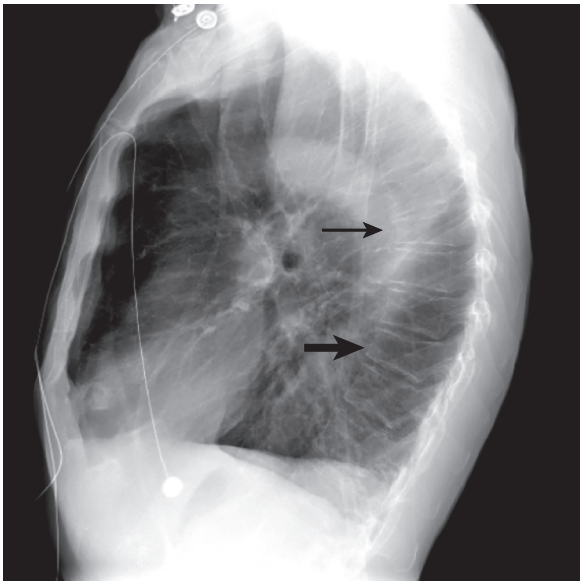

FIGURE 225-3. Incidental vertebral compression fractures on chest radiograph. Lateral radiograph of the chest of a 74-year-old man studied for cough. No relevant pulmonary abnormality was noted on the frontal radiograph (not shown). Examination of the thoracic spine shows the presence of a mild anterior wedge compression fracture of T9 *(thick arrow)* and moderate anterior wedge fracture of T6 (*thin arrow*). Neither fracture was reported on the radiographic report.

Bone mineral density is an independent predictor of future fracture, such that the relative risk for fracture increases by 1.5- to 2-fold for each 1 standard deviation decrease in T score. In addition, the risk of fracture increases exponentially below a T score of −2.5. A variety of other imaging techniques can assess bone mineral density (e.g., quantitative computed tomography [CT] or ultrasound),[10] but none are preferred over DXA scanning, which has a higher sensitivity for detecting osteoporosis and a better ability to follow bone density changes over time.

In addition to DXA, the continued development of additional imaging tools (HRpQCT and microMRI) may well further refine the risk for fragility fractures. Furthermore, the FDA recently approved biomechanical computed tomography (BCT) as an opportunistic assessment of bone mineral density and bone strength/fracture risk of the lumbar spine and proximal femur using CT imaging and finite element analysis, although it is not recommended to follow treatment response over time. At present, the use of BCT is likely most appropriate for patients who cannot undergo DXA imaging (e.g., patients with prior lumbar fusion or bilateral hip prostheses).

Although DXA is the best method to diagnose and manage osteoporosis, it cannot distinguish between low bone density and undermineralized bone matrix, the latter of which occurs in osteomalacia (Chapter 226). Bone mineral density also may be quite disparate between regions, perhaps in more than one third of individuals, especially in postmenopausal women, in patients taking corticosteroids, and in hyperparathyroidism. Degenerative changes due to aging, such as facet osteoarthritis and aortic calcification, may artifactually raise the spine bone mineral density. Given these considerations, the lowest skeletal site should be used for diagnosis. Finally, bone mineral density should be measured longitudinally on the same DXA machine, if possible, because of intermachine and intermanufacturer differences that may confound the ability to measure change over time validly.[11]

Despite its utility, bone density is limited in its ability to future predict fractures in individual patients,[12] because it does not take into account clinical factors that independently predict risk.[13] The most widely used of these prediction model is FRAX, which calculates a person's 10-year risk for hip and major osteoporotic fracture (hip, clinical spine, forearm, and proximal humerus all combined) using country-specific data on clinical risk factors as well as bone mineral density of the femoral neck (E-Fig. 225-4 and http://www.shef.ac.uk/FRAX/). FRAX does not consider a patient's history of or risk for falls. The U.S. Preventive Services Task Force recommends DXA screening for osteoporosis routinely in women over age 65 years but that screening in women younger than 65 years should consider a number of formal clinical risk

assessment tools, such as FRAX (E-Fig. 225-4 and http://www.shef.ac.uk/FRAX), which is the most robust complementary tool to bone mineral density for defining a person's risk for fracture and candidacy for pharmacologic intervention, and test only if the risk is a major osteoporotic fracture is 8.4% or greater by FRAX assessment.[14,A1] Combining FRAX with use of a trabecular bone score (E-Fig. 225-5), which is a surrogate measure of bone architecture that can be performed at the same time as DXA scanning, may better predict the risk for hip and major osteoporotic fractures, though it is not used widely in clinical practice at the present time.

Search for Causes of Bone Loss

About 20 to 25% of women and perhaps an even greater proportion of men will have identifiable additional etiologies that may contribute to bone loss (see Table 225-1). Although a recent fragility fracture with a consistent radiographic finding or a DXA scan result is a reasonable basis for diagnosis of osteoporosis, other skeletal conditions also should be entertained, including inherited and acquired osteomalacias (Chapter 226) and pathologic fracture due to malignancy, especially multiple myeloma (Chapter 173) or metastatic cancer of bone (Chapter 187). Most patients will already have had routine chemistry, hematology, and thyroid studies as part of their annual examination. The 25(OH)D level should be measured in all patients. Additional investigations may also be considered, as directed by the clinical history and physical examination. In addition, a greater degree of bone mineral density deficit (i.e., lower Z score) indicates a need for more extensive testing, given the greater likelihood of secondary causes being present. Bone turnover markers (e.g., bone-specific alkaline phosphatase, osteocalcin, type I procollagen amino-terminal propeptide, and type I procollagen carboxy-terminal propeptide as formation markers, and serum and urine C- and N-terminal peptides of type I collagen as resorption markers) should not be used in routine clinical practice but occasionally help experts manage more complicated cases of metabolic bone disease.

TABLE 225-2 TREATMENT BASED ON THE RISK OF FRACTURE

LEVEL OF FRACTURE RISK	CRITERIA	TREATMENT
Low	T score > –1.0 AND no hip or vertebral fracture, AND FRAX hip fracture < 3% and major osteoporotic fracture risk < 20%	Nonpharmacologic (calcium/vitamin D and exercise)
Moderate	T score > –2.5 AND no hip or vertebral fracture AND FRAX hip fracture < 3% and major osteoporotic fracture risk < 20%	Nonpharmacologic OR bisphosphonate
High	T score ≤ –2.5 OR prior hip or vertebral fracture OR FRAX hip fracture > 3% and major osteoporotic fracture risk > 20%	Bisphosphonate Denosumab Selective estrogen receptor modulator
Very High	T score ≤ –2.5 and fractures AND multiple vertebral fractures OR severe vertebral fracture (>40% vertebral height loss)	Anabolic agent Bisphosphonate Denosumab

Major fracture risk refers to a 10-year risk of a fracture of the hip, clinical spine, distal forearm, or proximal humerus. Severe describes the degree of vertebral body compression fracture (mild 20% to 25%, moderate 25% to 40%, and severe >40%).

Adapted from Shoback D, Rosen CJ, Black DM, et al. Pharmacological management of osteoporosis in postmenopausal women: an Endocrine Society guideline update. *J Clin Endocrinol Metab*. 2020;105:587-594.

PREVENTION AND TREATMENT

The approach to the patient with osteoporosis should be guided by the risk for fracture (Table 225-2 and http://www.shef.ac.uk/FRAX/).[15]

Calcium and Vitamin D

Adequate intake of calcium is critical to the optimal accumulation and maintenance of bone mineral density. Although calcium supplementation modestly improves bone mineral density by 1 to 2%, it does not independently reduce the risk of hip and nonvertebral fractures in patients with osteoporosis.[A2] Given the established increased risk of nephrolithiasis (Chapter 111) and a potential increase in nonfatal cardiac events with higher dose calcium supplementation,[16] adults with osteoporosis should obtain 1200 to 1500 mg of calcium primarily from dietary sources, with the adjunct use of calcium supplements as needed to achieve this goal.

Data in adults with osteopenia and osteoporosis confirm a benefit of combined vitamin D and calcium supplementation (400 to 800 IU of vitamin D combined with 1000 mg of calcium) to reduce the risk for hip fracture in postmenopausal women and men aged 65 years and older, but this benefit is small or nonexistent in community-dwelling individuals.[A3] Although some data suggest that a 25(OH)D level of at least 30 ng/mL is needed to reduce the risk for hip fracture, there is considerable controversy as to whether a vitamin D level above 30 ng/mL reduces the overall risk for fracture.[A4] Given these observations, a minimal 25 (OH)D level of 20 ng/mL is recommended for bone health.

In individuals without osteopenia or osteoporosis, routine vitamin D supplementation (with or without calcium supplementation) does not appear to prevent falls or fractures in community-dwelling adults who do not have vitamin D deficiency or prior fractures,[A5,A6] even in the presence of vitamin insufficiency (serum 25(OH) D levels less than 20 to 30 ng/mL).[A7] Although activated vitamin D analogues such as calcitriol and α-calcidiol may reduce the risk of fracture, they are generally not indicated based on unacceptable risk for hypercalcemia. The exception is to use vitamin D analogues in patients with stages 3 and 4 chronic kidney disease (Chapter 116), in which treatment of secondary hyperparathyroidism may provide skeletal benefit.

Exercise and Lifestyle

Physical activity is also critical for preventing osteoporosis and its progression.[A8] Exercise modestly improves bone mineral density in the lumbar spine (mean difference = 0.85%) and trochanter (mean difference = 1.03% in postmenopausal women), but it does not significantly improve femoral neck or total hip bone mineral density.[17] Physical activity also enhances muscle strength, improves cardiovascular status, and thereby reduces the risk of falls. Balance training and Tai Chi also reduce the risk for falling (see Chapter 24). Tobacco cessation and moderation of caffeine and alcohol intake may be helpful, but data are not available as to whether these interventions reduce overall risk of fracture.

Medications

Pharmacologic therapy, which should be based on a patient's risk for an osteoporotic fracture (see Table 225-2 and Fig. 225-4), significantly reduces the risk for osteoporotic fracture in a clinically meaningful and cost-effective manner.[18,19] A FRAX (http://www.shef.ac.uk/FRAX/) 10-year risk equal to or exceeding 3% for hip fracture and 20% for major fracture warrants consideration of pharmacologic treatment. Because medications reduce the relative risk of hip fracture by about 50%, or from about 10% to about 5% in patients with osteoporosis, about 20 patients need to be treated to prevent one hip fracture.

Medications approved for osteoporosis can be classified based on their mechanism of action: anticatabolic (i.e., antiresorptive) and anabolic (i.e., bone building).[20,21] The choice among available agents is guided by the level of risk of fractures (Table 225-2).

Anticatabolic Agents

Anticatabolic (or antiresorptive) medications inhibit the recruitment, function, and/or survival of osteoclasts, thereby resulting in reductions in skeletal turnover and bone loss. These agents improve bone mineral density, strengthen the skeletal microstructure, and reduce the risk of fracture.

Bisphosphonates

Bisphosphonates are the most widely prescribed and used medications for the treatment of osteoporosis, owing in large part to good tolerability and infrequent dosing. Bisphosphonates, which have an extremely high affinity for hydroxyapatite crystals within bone, are taken up by osteoclasts and inhibit their cellular attachment, function, and survival.

ORAL BISPHOSPHONATES. Oral agents are first-line therapy. Three oral bisphosphonates are currently available in the United States: once-weekly alendronate, once-weekly or once-monthly risedronate, and once-monthly ibandronate. Oral bisphosphonates should be taken fasting in the morning with water only, and the patient must remain fasting in a sitting or standing position for 30 to 60 minutes after the dose. The most common side effect is precipitation or aggravation of gastroesophageal reflux, although most patients tolerate the drugs without difficulty. A delayed-release formulation of risedronate may be taken immediately after breakfast, thereby likely lessening the risk for reflux-related symptoms. These drugs are contraindicated in patients with functional or anatomic disorders of esophageal transit (i.e., esophageal stricture, achalasia) or advanced renal insufficiency (i.e., a glomerular filtration rate <35 mL/min). All three drugs significantly increase bone mineral density and reduce the risk for vertebral fractures at 12 months.[A9] Data also strongly support a persistent antifracture benefit following cessation of treatment if it has been used continuously for at least 5 years (Table 225-3).

Calculation Tool

Please answer the questions below to calculate the ten year probability of fracture with BMD.

Country: US (Caucasian) Name/ID:

Questionnaire:

1. Age (between 40 and 90 years) or Date of Birth
   Age: Date of Birth: Y: M: D:
2. Sex ○ Male ○ Female
3. Weight (kg)
4. Height (cm)
5. Previous Fracture ○ No ○ Yes
6. Parent Fractured Hip ○ No ○ Yes
7. Current Smoking ○ No ○ Yes
8. Glucocorticoids ○ No ○ Yes
9. Rheumatoid arthritis ○ No ○ Yes
10. Secondary osteoporosis ○ No ○ Yes
11. Alcohol 3 or more units/day ○ No ○ Yes
12. Femoral neck BMD (g/cm^2)

Select BMD

Clear Calculate

For USA use only

Consider FDA-approved medical therapies in postmenopausal women and men aged 50 years and older, based on the following:

- A hip or vertebral (clinical or morphometric) fracture
- T-score ≤ –2.5 at the femoral neck or spine after appropriate evaluation to exclude secondary causes
- Low bone mass (T-score between –1.0 and –2.5 at the femoral neck or spine) and a 10-year probability of a hip fracture ≥ 3% or a 10-year probability of a major osteoporosis-related fracture ≥ 20% based on the US-adapted WHO algorithm
- Clinicians judgment and/or patient preferences may indicate treatment for people with 10-year fracture probabilities above or below these levels

Risk factors

For the clinical risk factors a yes or no response is asked for. If the field is left blank, then a "no" response is assumed. See also notes on risk factors.

The risk factors used are the following:

Age	The model accepts ages between 40 and 90 years. If ages below or above are entered, the programme will compute probabilities at 40 and 90 year, respectively.
Sex	Male or female. Enter as appropriate.
Weight	This should be entered in kg.
Height	This should be entered in cm.
Previous fracture	A previous fracture denotes more accurately a previous fracture in adult life occurring spontaneously, or a fracture arising from trauma which, in a healthy individual, would not have resulted in a fracture. Enter yes or no (see also notes on risk factors).
Parent fractured hip	This enquires for a history of hip fracture in the patient's mother or father. Enter yes or no.
Current smoking	Enter yes or no depending on whether the patient currently smokes tobacco (see also notes on risk factors).
Glucocorticoids	Enter yes if the patient is currently exposed to oral glucocorticoids or has been exposed to oral glucocorticoids for more than 3 months at a dose of prednisolone of 5 mg daily or more (or equivalent doses of other glucocorticoids) (see also notes on risk factors).
Rheumatoid arthritis	Enter yes where the patient has a confirmed diagnosis of rheumatoid arthritis. Otherwise enter no (see also notes on risk factors).
Secondary osteoporosis	Enter yes if the patient has a disorder strongly associated with osteoporosis. These include type I (insulin dependent) diabetes, osteogenesis imperfecta in adults, untreated long-standing hyperthyroidism, hypogonadism or premature menopause (<45 years), chronic malnutrition, or malabsorption and chronic liver disease
Alcohol 3 or more units/day	Enter yes if the patient takes 3 or more units of alcohol daily. A unit of alcohol varies slightly in different countries from 8–10g of alcohol. This is equivalent to a standard glass of beer (285ml), a single measure of spirits (30ml), a medium-sized glass of wine (120ml), or 1 measure of an aperitif (60ml) (see also notes on risk factors).
Bone mineral density (BMD)	(BMD) Please select the make of DXA scanning equipment used and then enter the actual femoral neck BMD (in g/cm^2). Alternatively, enter the T-score based on the NHANES III female reference data. In patients without a BMD test, the filed should be left blank (see also notes on risk factors) (Provided by Oregon Osteoporosis Center).

Notes on risk factors

Previous fracture

A special situation pertains to a prior history of vertebral fracture. A fracture detected as a radiographic observation alone (a morphometric vertebral fracture) counts as a previous fracture. A prior clinical vertebral fracture or a hip fracture is an especially strong risk factor. The probability of fracture computed may therefore be underestimated. Fracture probability is also underestimated with multiple fractures.

Smoking, alcohol, glucocorticoids

These risk factors appear to have a dose-dependent effect, i.e. the higher the exposure, the greater the risk. This is not taken into account and the computations assume average exposure. Clinical judgement should be used for low or high exposures.

Rheumatoid arthritis (RA)

RA is a risk factor for fracture. However, osteoarthritis is, if anything, protective. For this reason reliance should not be placed on a patient's report of 'arthritis' unless there is clinical or laboratory evidence to support the diagnosis.

Bone mineral density (BMD)

The site and reference technology is DXA at the femoral neck. T-scores are based on the NHANES reference values for women aged 20–29 years. The same absolute values are used in men.

Adapted with permission from Levis S, Theodore G. Summary of AHRQ's comparative effectiveness review of treatment to prevent fractures in men and women with low bone density or osteoporosis: update of the 2007 report. *J Manag Care Pharm*. 2012;18(4 Suppl B):S1-S15, discussion S13.

PARENTERAL BISPHOSPHONATES. Parenteral bisphosphonates are second-line alternative options for patients who have contraindications to oral bisphosphonates (e.g., esophageal disease, inability to sit upright and/or fast after dose), documented or expected poor adherence to oral bisphosphonates, or failure to respond to oral bisphosphonates or other therapies that are approved by the U.S. Food and Drug Administration (FDA) as evidenced by recurrent fractures and declining bone mineral density. Zoledronic acid (5 mg once yearly), reduces the risk of spine, hip, and nonvertebral fractures in women and men.[A10] Zoledronic acid also reduces mortality in women and men following a low-trauma hip fracture,[A11] although the mechanism of this mortality benefit is unknown. Bone mineral density remains stable, and the antifracture effect likely persists for 3 years after three to six annual doses of zoledronic acid.[A12] Furthermore, less frequent (5 mg every 18 months) dosing of zoledronate significantly reduces the risk for vertebral and nonvertebral fragility fractures in older women who have osteopenia but who do not meet criteria for osteoporosis.[A13] Ibandronate (3 mg every 3 months) is an intravenous alternative, but data on its benefits are not as robust as for zoledronic acid.

COMPLICATIONS OF BISPHOSPHONATES. Both intravenous bisphosphonates are associated with an approximately 15 to 20% likelihood of a flulike or acute phase reaction, typically consisting of fever, arthralgias, and myalgias, usually limited to the first infusion and generally persisting 24 to 48 hours. Higher serum levels of 25(OH)D (>30 ng/mL) and previous oral bisphosphonate treatment appear to lessen the severity of these reactions.[22]

A rare but serious adverse effect of both oral and intravenous bisphosphonates is osteonecrosis of the jaw (Chapter 229),[23] which is defined as exposed bone within the oral cavity for more than 8 weeks following an invasive dental procedure (e.g., tooth extraction, dental implant) or spontaneous tooth loss. Osteonecrosis occurs in roughly 1 in 10,000 to 100,000 patients treated with oral bisphosphonates, although it likely occurs in 1 in 1000 to 10,000 patients who are treated with intravenous bisphosphonates for osteoporosis. Patients on intravenous bisphosphonates should maintain optimal oral hygiene and consider a bisphosphonate holiday or delay in dose if invasive oral procedures are planned.

Another risk is atypical femoral fractures, which generally occur after 5 years or more of bisphosphonate therapy.[24] The estimated risk is low (about 1 in 5000 to 10,000) but increases significantly with longer use (about 1/900 risk with 8 to 10 years of continuous treatment) and is eight-fold higher in Asians than Whites for unclear reasons. Patients will typically have prodromal thigh or groin pain, which can refer to a stress fracture of a thickened lateral femoral cortex, inferior to the greater trochanter. These fractures can be bilateral and may be identified radiographically with plain films, MRI, or CT. Femoral and cortical thickening, periosteal reaction, or a medial spike on plain radiograph, or a more extensive assessment of the proximal femur on DXA scan may identify patients at risk for these fractures.

Although rare, the severe manifestations of osteonecrosis of the jaw and atypical femoral fractures make it prudent for clinicians to consider a drug holiday (i.e., cessation), particularly given strong evidence of continued benefit on discontinuation after 3 to 5 years of continuous therapy (3 years for intravenous and 5 years for oral). Although the duration of bisphosphonate drug holidays has not been defined and must be individualized, patients may subsequently restart a bisphosphonate or another osteoporosis therapy if clinically indicated based on their level of fracture risk.

Denosumab

Denosumab, which is a fully humanized monoclonal antibody to RANKL, is approved by the FDA for the treatment of osteoporosis in postmenopausal women and in men, as well as for individuals with breast and prostate cancer, to reduce bone loss associated with hormone deprivation. Administered twice yearly as a subcutaneous injection (in a medical facility), it reduces the risk for spine, hip, and nonvertebral fractures in women and vertebral fractures in men,[A14,A15] with a significantly greater improvement in bone mineral density compared with bisphosphonates.[A16] Denosumab does not undergo hepatic or renal metabolism and thus can potentially be used in patients with more advanced renal dysfunction. Unlike bisphosphonates, it is reversible, such that robust bone loss ensues after the medication is stopped, and "rebound" fractures may occur if denosumab is discontinued. As a result, an oral bisphosphonate (6 months after discontinuation) or an intravenous bisphosphonate (7 to 8 months after the last dose of denosumab) should be started after it is discontinued.[25] Although clinical trial data demonstrate effectiveness for up to 10 years of continuous use, a longer duration of denosumab use is associated with greater risk for bone loss despite subsequent use of bisphosphonates.[26] Denosumab is well tolerated but is associated with a higher incidence of skin conditions (eczema and erysipelas) and infections, including serious infections that required hospitalization.[27] Therefore, the drug is likely not suitable for patients who are immunosuppressed or at increased risk for infection.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators bind to the estrogen receptor and thereby serve as anticatabolic agents in bone. Raloxifene, which reduces the risk for vertebral fractures by approximately 30 to 50% but does not reduce the risk for hip and nonvertebral fractures, is an alternative to bisphosphonates in postmenopausal women who have osteopenia and a relatively low risk for hip and other nonspine fractures. Raloxifene is known to be safe and effective over 8 years of continuous use, and the optimal duration of use is uncertain. The most common side effects include hot flushes and leg cramps in about 10 to 15% of patients and about 5% of patients, respectively. Selective estrogen receptor modulators also increase the risk for deep vein thrombosis, with an absolute risk of about 1 in 400, akin to that seen with oral estrogen hormone replacement therapy. Raloxifene has also been associated with an increased risk for fatal stroke in women at higher baseline risk for stroke, likely precluding its general consideration in women older than age 65 years. Another selective estrogen receptor modulator (bazedoxifene) reduces vertebral fractures by 42% and is available in a fixed combination with conjugated estrogens 0.45 mg for osteoporosis prophylaxis.

Estrogen

Estrogen replacement therapy prevents bone loss if administered to women at menopause and significantly increases bone mineral density by approximately 3 to 5% in woman who are well into their menopausal years. Although lower doses of estrogen may have skeletal benefits, more standard doses of estrogen (0.625 mg of conjugated equine estrogen and 1.0 mg of ethinyl estradiol) have been proved efficacious. Long-term estrogen therapy reduces the risk for all clinical fractures by about 27%.[A17] However, estrogen replacement therapy is associated with other risks (Chapter 222), so it is generally recommended for osteoporosis only in postmenopausal women who are at significant risk for fracture and for whom other antifracture therapies are unsuitable.[28]

Anabolic Agents

Teriparatide

Teriparatide, which is a recombinant human parathyroid hormone analogue that encompasses amino acids 1 to 34, is prescribed as a self-administered, once-daily, subcutaneous injection. Teriparatide increases bone density in the lumbar spine by about 10% over 2 years and significantly reduces the risk for vertebral fractures by approximately two thirds and nonvertebral fractures by about 50%.[A18] Teriparatide or its generic biosimilar at the same dose is generally recommended as second-line therapy for patients who have severe osteoporosis, based on bone mineral density and/or their risk of fracture, and who cannot tolerate or have contraindications to other antifracture agents.

Because bone resorption increases along with bone formation, bone loss generally ensues on cessation of therapy, thereby necessitating the initiation of an anticatabolic bone drug to preserve its increase in bone mineral density. The combination of teriparatide plus denosumab may have a synergistic effect on bone mineral density,[29] but data on the benefit of combining teriparatide with it or a bisphosphonate are inconclusive. Teriparatide should not be used after denosumab therapy, based on a proven decrease in bone mineral density when this sequence is administered.

The drug is generally well tolerated, with the most common adverse effects being dizziness and leg cramps. Hypercalcemia is a rare side effect that may be seen in patients who have undiagnosed primary hyperparathyroidism before treatment. Teriparatide may increase the risk for osteosarcoma based on animal studies, so the drug is limited to a lifetime total duration of 24 months of use and is contraindicated in patients who are at a higher baseline risk for osteosarcoma (e.g., patients with Paget disease or previous therapeutic radiotherapy, as well as younger individuals with open epiphyses).

Abaloparatide

Abaloparatide (a selective activator of the parathyroid hormone type 1 receptor; administered as 80 μg subcutaneously daily) is as effective as teriparatide for reducing fractures in postmenopausal women with osteoporosis and is associated with a lower risk of hypercalcemia.[A19] Similar to teriparatide, it is potentially linked to a higher risk for osteosarcoma based on rat toxicology data and is limited to 24 months total of lifetime use.

Romosozumab

Romosozumab (210 mg given monthly by subcutaneous injection for 1 year), which is a humanized monoclonal antibody against sclerostin, is effective for the treatment of postmenopausal osteoporosis. It significantly increases bone mineral density and reduces the risk for osteoporotic vertebral fractures by 75% at 1 year, which is the recommended duration of therapy.[A20] Unlike teriparatide, inhibition of sclerostin does not appear to stimulate bone resorption, thereby potentially affording greater and more persistent gains in bone mineral density. Romosozumab increases the risk of cardiovascular events compared with alendronate and is therefore contraindicated in women who have had a myocardial infarction or a stroke within 1 year before treatment. Given that the drug also has antiosteoclastic effects through the Wnt pathway, it may also increase the risk for rare events (osteonecrosis of the jaw and atypical femoral fractures) that are seen with antiresorptive therapies.

Other Therapies

Nasal calcitonin is FDA-approved for treating postmenopausal osteoporosis, but it is widely considered the weakest antifracture agent based on its marginal benefits. In addition, its possible link to cancer further limits its clinical utility and future availability in the United States.

Strontium ranelate, which is approved in Europe (but not available for use in the United States) for the treatment of osteoporosis, may have a dual proformation-anticatabolic effect on bone. It reduces the risk for vertebral and nonvertebral fractures as well as clinical osteoporotic fractures. Because of artifactual increases in bone mineral density related to the incorporation of the strontium salt into bone, serial DXA scanning cannot be followed in patients on strontium.

Drug Combinations and Sequencing

Current guidelines support the initial use of an anabolic therapy in patients with more severe deficits in bone mineral density and/or a high risk of fracture, followed immediately by an antiresorptive agent to prevent the bone loss that occurs with cessation of the anabolic agent. Conversely, parathyroid hormone analogues are not recommended after denosumab because of expected bone loss that occurs with this sequence.

Combination therapy with an antiresorptive agent and an anabolic agent is not currently recommended due to both cost and lack of a clear benefit. Some data, however, suggest that combination therapy may provide additional improvements in bone mineral density and possibly additional reduction in the risk of fracture compared with monotherapy,[A21] likely related to the finding that the degree of increase in bone mineral density at the lumbar spine and hip correlate with the degree to which the risk of fracture is reduced.[30] These data also suggest that future treatments may be targeted to a bone mineral density goal.

Glucocorticoid-Induced Osteoporosis

Glucocorticoids, which are potent suppressors of bone formation and at higher doses likely also increase bone resorption, are the most common cause of medication-related secondary osteoporosis. The result can be a dramatic decline in bone mineral density within the first 6 months of starting therapy. The risk of fracture is increased as well, even with prednisone doses as low as 2.5 mg per day, although the increase in risk appears to attenuate when the glucocorticoid is discontinued.

The treatment approach to glucocorticoid-induced osteoporosis is similar to that osteoporosis in general,[31] with the exception that attempts should first try to reduce the glucocorticoid dose to as low as the underlying treated disease will permit. Calcium and vitamin D at doses generally recommended for postmenopausal osteoporosis are important adjuncts but are insufficient to prevent bone loss or fractures. Although bisphosphonates are effective for glucocorticoid-induced osteoporosis in women and men,[A22] data indicate that either denosumab or teriparatide is superior to bisphosphonates in these patients.[A23] Options include 60 mg of subcutaneous denosumab every 6 months[A24] while patients are on glucocorticoid therapy or teriparatide[A25] but for no more than 24 months overall.

Vertebroplasty, Kyphoplasty, and Low-Intensity Vibration

Although often clinically silent, vertebral fractures may cause acute and severe back pain. In addition, up to one third of vertebral fractures remain chronically painful, perhaps related to incomplete healing or instability of the fracture. Vertebroplasty and kyphoplasty are invasive procedures that introduce, through the spinal pedicles, a cement-like substance (polymethylmethacrylate) into the compressed vertebral body, with (kyphoplasty) or without (vertebroplasty) use of saline-infused balloon tamps that permit a few millimeters of elevation of the vertebral end plates. Initial randomized trials in patients with acute vertebral fractures were promising, but overall data have shown little or no benefit versus conservative treatment (i.e., pain management),[A26] even if the procedure is performed soon after the acute fracture.

Low-intensity vibration is diagnosed to enhance the development of osteoblasts and hinder the development of osteoclasts, thereby "coupling" bone remodeling. Early studies suggested a modest but significant benefit on bone mineral density, but overall data show no benefit on bone mineral density or bone turnover markers.[A27]

Male Osteoporosis

Male osteoporosis historically has been underrecognized and underappreciated, but more than 2 million men in the United States have osteoporosis, 1 in 4 men older than age 50 years will suffer a fragility fracture in their remaining lifetime, and about 30% of vertebral and hip fractures occur in men.[32] In addition, men have a substantially higher mortality after hip fracture compared with women. Aging, low body weight, and prior fragility fractures are independent predictors of future fracture in men, but common secondary causes include glucocorticoid use, alcohol overuse, hypogonadism, and lower production and circulating levels of estrogen.

Despite these risks, a DXA screening strategy is not recommended to identify men at higher risk for fracture, except perhaps in men who have a high prior probability of fracture.[33] The laboratory evaluation of male osteoporosis is similar to that for women, with the exception that fasting morning testosterone level should be obtained.

TREATMENT

The primary treatment of male osteoporosis is targeted at lifestyle changes, adequate nutrition (calcium and vitamin D), and exercise. Bisphosphonates (oral and intravenous), denosumab, and teriparatide are all effective at improving bone mineral density in men, although the antifracture efficacy of non-bisphosphonates in men is less clear,[A28] except for denosumab in men who have prostate cancer and are on androgen deprivation therapy (Chapter 186). Testosterone replacement in men with significant biochemical hypogonadism (total T score <200 ng/dL) improves bone density, although data on reducing the risk of fracture are lacking. In older men (age >50 years) at a substantial risk for fracture based on history and risk factors, androgen replacement should be considered second-line or adjunctive therapy after or with specific anti-osteoporosis therapies, based on overall risk-benefit and lack of antifracture efficacy data to date.

PROGNOSIS

The osteoporotic burden incurred by individual patients and society as a whole can be significantly lessened by a combination of diagnostic, preventive, and therapeutic interventions. Although osteoporosis cannot be cured, current pharmacotherapies that increase bone mineral density are associated with about a 50% reduced risk for subsequent fractures. Moreover, available data confirm a statistically significant reduction in death with pharmacologic treatment of osteoporosis. This reduction is critical because robust evidence suggests an independent increase in mortality after an osteoporotic fracture, including fractures of the spine, proximal femur, humerus, tibia, and pelvis. These data underscore the importance of identifying and treating patients with osteoporosis.

226 OSTEOMALACIA AND RICKETS

ROBERT S. WEINSTEIN

DEFINITION

Rickets can no longer be considered a historical disorder limited to third world countries or poor people. The COVID-19 pandemic and the loss of school dairy products in the United States has increased malnutrition and vitamin D deficiency. The primary function of vitamin D is to provide adequate levels of calcium and phosphorus by increasing their intestinal absorption, thereby making them available for normal mineralization of bone and epiphyseal cartilage. Rickets, which occurs in growing children, affects both the cartilaginous growth plate and bone, where it causes characteristic deformities. Osteomalacia, which occurs after growth has ceased, has more subtle manifestations that are frequently overlooked.

Normal mineralization requires the availability of sufficient calcium and phosphorus, the presence of normal bone collagen, the absence of inhibitors of mineralization, and an adequate amount of bone alkaline phosphatase activity. Defects in these requirements are the cause of most forms of osteomalacia. Deficiency of vitamin D in isolation has traditionally been incriminated as the cause of the osteomalacia, but today, considerable evidence indicates that the abnormal mineralization associated with vitamin D deficiency is due to inadequate calcium and phosphorus rather than the absence of a direct effect of vitamin D on bone cells. Optimal therapy requires precise identification of the etiology of the abnormal mineralization (Table 226-1), and thereby is often gratifying.

EPIDEMIOLOGY

Nutritional rickets continues to be an evolving and multifactorial problem worldwide.[1,2] About 25% of women in the United States have 25-hydroxyvitamin D levels below 20 ng/mL (adequate values are greater than 30 ng/mL), and 8% have levels below 12 ng/mL, thereby indicating that impaired bone mineralization could be a confounding factor in the treatment of their osteoporosis and that osteomalacia (defective mineralization) rather than osteoporosis (reduced amount of normally mineralized bone) is the underlying problem.

Osteomalacia and vitamin D deficiency must be excluded before administration of the antiresorptive drugs used for postmenopausal osteoporosis (Chapter 225), particularly before the use of zoledronate or denosumab, which will induce hypocalcemia and secondary hyperparathyroidism if vitamin D levels are inadequate. Vitamin D deficiency is a particular problem in the nonaffluent elderly and individuals with self-imposed diets that avoid meat, dairy products, and fish. Vitamin D deficiency is also commonly found in medical inpatients and in postmenopausal women with an acute hip fracture. The prevalence of osteomalacia due to vitamin D deficiency varies; at greatest risk are incarcerated patients, patients with cystic fibrosis (Chapter 77), gastric bypass surgery (Chapter 201), or patients who have hyperparathyroidism (Chapter 227), that is actually secondary to vitamin D deficiency. Also at risk are individuals who live in chronic care facilities or who have nonhealing fractures.

X-linked hypophosphatemia, which is the most common inherited form of hypophosphatemic osteomalacia, has a prevalence of 1:20,000.

PATHOBIOLOGY

The abnormal mineralization characteristic of osteomalacia is due to slowed or terminated mineral deposition in the organic matrix of bone (osteoid) because of one or more of the defects mentioned earlier. However, osteoblasts continue to make osteoid, which then accumulates in excessive amounts. Histologically, the osteoid width may become dramatically augmented (Fig. 226-1). Depending on the extent of the mineralization delay, overt osteomalacia may take many years to develop. After normalization of the serum calcium and phosphorus levels, bone healing may take at least 6 to 18 months.

226 OSTEOMALACIA AND RICKETS

ROBERT S. WEINSTEIN

DEFINITION

Rickets can no longer be considered a historical disorder limited to third world countries or poor people. The COVID-19 pandemic and the loss of school dairy products in the United States has increased malnutrition and vitamin D deficiency. The primary function of vitamin D is to provide adequate levels of calcium and phosphorus by increasing their intestinal absorption, thereby making them available for normal mineralization of bone and epiphyseal cartilage. Rickets, which occurs in growing children, affects both the cartilaginous growth plate and bone, where it causes characteristic deformities. Osteomalacia, which occurs after growth has ceased, has more subtle manifestations that are frequently overlooked.

Normal mineralization requires the availability of sufficient calcium and phosphorus, the presence of normal bone collagen, the absence of inhibitors of mineralization, and an adequate amount of bone alkaline phosphatase activity. Defects in these requirements are the cause of most forms of osteomalacia. Deficiency of vitamin D in isolation has traditionally been incriminated as the cause of the osteomalacia, but today, considerable evidence indicates that the abnormal mineralization associated with vitamin D deficiency is due to inadequate calcium and phosphorus rather than the absence of a direct effect of vitamin D on bone cells. Optimal therapy requires precise identification of the etiology of the abnormal mineralization (Table 226-1), and thereby is often gratifying.

EPIDEMIOLOGY

Nutritional rickets continues to be an evolving and multifactorial problem worldwide.[1,2] About 25% of women in the United States have 25-hydroxyvitamin D levels below 20 ng/mL (adequate values are greater than 30 ng/mL), and 8% have levels below 12 ng/mL, thereby indicating that impaired bone mineralization could be a confounding factor in the treatment of their osteoporosis and that osteomalacia (defective mineralization) rather than osteoporosis (reduced amount of normally mineralized bone) is the underlying problem.

Osteomalacia and vitamin D deficiency must be excluded before administration of the antiresorptive drugs used for postmenopausal osteoporosis (Chapter 225), particularly before the use of zoledronate or denosumab, which will induce hypocalcemia and secondary hyperparathyroidism if vitamin D levels are inadequate. Vitamin D deficiency is a particular problem in the nonaffluent elderly and individuals with self-imposed diets that avoid meat, dairy products, and fish. Vitamin D deficiency is also commonly found in medical inpatients and in postmenopausal women with an acute hip fracture. The prevalence of osteomalacia due to vitamin D deficiency varies; at greatest risk are incarcerated patients, patients with cystic fibrosis (Chapter 77), gastric bypass surgery (Chapter 201), or patients who have hyperparathyroidism (Chapter 227), that is actually secondary to vitamin D deficiency. Also at risk are individuals who live in chronic care facilities or who have nonhealing fractures.

X-linked hypophosphatemia, which is the most common inherited form of hypophosphatemic osteomalacia, has a prevalence of 1:20,000.

PATHOBIOLOGY

The abnormal mineralization characteristic of osteomalacia is due to slowed or terminated mineral deposition in the organic matrix of bone (osteoid) because of one or more of the defects mentioned earlier. However, osteoblasts continue to make osteoid, which then accumulates in excessive amounts. Histologically, the osteoid width may become dramatically augmented (Fig. 226-1). Depending on the extent of the mineralization delay, overt osteomalacia may take many years to develop. After normalization of the serum calcium and phosphorus levels, bone healing may take at least 6 to 18 months.

ABSTRACT

Rickets can no longer be considered a historical disorder limited to third world countries or poor people. The COVID-19 pandemic and the loss of school dairy products has increased malnutrition in the United States, and vitamin D deficiency is increasingly prevalent. The primary function of vitamin D is to provide adequate levels of calcium and phosphorus by increasing their intestinal absorption, thereby making them available for normal mineralization of bone and epiphyseal cartilage. Rickets occurs in growing children, and both the cartilaginous growth plate and bone are affected, thereby causing characteristic deformities. Osteomalacia, which occurs after growth has ceased, has more subtle manifestations that are frequently overlooked. Normal mineralization requires the availability of sufficient calcium and phosphorus, the presence of normal bone collagen, the absence of inhibitors of mineralization, and an adequate amount of bone alkaline phosphatase activity. Defects in these requirements are the cause of most forms of osteomalacia. Considerable evidence indicates that the abnormal mineralization associated with vitamin D deficiency is due to inadequate calcium and phosphorus rather than the absence of a direct effect of vitamin D on bone cells. After a correct diagnosis is made, therapy is often gratifying.

KEYWORDS

osteoid
25-hydroxyvitamin D
X-linked hypophosphatemia
autosomal dominant hypophosphatemic rickets
tumor-induced osteomalacia
vitamin D-dependent rickets
hypophosphatasia

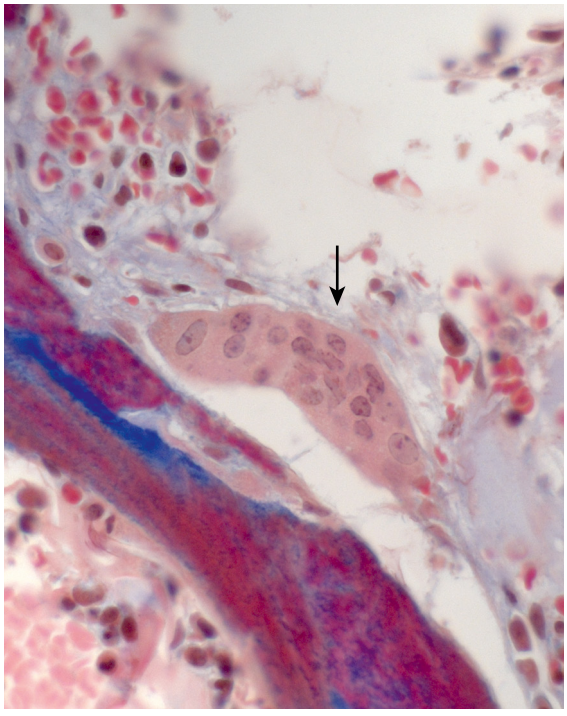

FIGURE 226-1. An undecalcified bone biopsy specimen shows the characteristic abundant osteoid and flattened osteoblasts of osteomalacia. The detached giant osteoclast (see *arrow*) containing more than 20 nuclei is a result of treating this patient with alendronate because of an incorrect diagnosis of osteoporosis. (Normally, mineralized bone appears blue and osteoid is carmine.)

X-linked hypophosphatemia, hypophosphatemic rickets, and tumor-induced osteomalacia are due to increased (or inappropriate for the low serum phosphate) serum fibroblast growth factor 23 (FGF-23) levels that cause excessive phosphaturia and inhibition of 25-hydroxyvitamin D-1α-hydroxylase. The hypophosphatemia is intensified by the inappropriately low levels of 1,25-dihydroxyvitamin D. Tumor-induced osteomalacia is a rare form of acquired, paraneoplastic, hypophosphatemic osteomalacia due to a small and often hard-to-find benign mesenchymal tumor (Chapter 187).[3]

Hypophosphatemic osteomalacia and fractures may occur after the administration of intravenous ferric carboxymaltose for refractory iron deficiency anemia. The hypophosphatemia may be detected within 1 week of the infusion, persist, and be accompanied by a two- to four-fold increase in FGF-23. This complication does not occur with administration of ferumoxytol.[4]

Osteomalacia also can be caused by inhibitors of mineralization such as etidronate (the first oral bisphosphonate, now rarely used in North America), high doses of fluoride (in bulk tea), the accumulation of a skeletal burden of aluminum from water used for dialysis (now rarely seen), iron overload as in thalassemia, and from high pyrophosphate levels in hypophosphatasia. Cholestyramine therapy for cholestasis or laxative abuse may also cause malabsorption and resistance to vitamin D supplements. Cadmium, tenofovir, or adefovir may induce Fanconi syndrome and cause osteomalacia due to the resultant hypophosphatemia.

Several presumed causes of osteomalacia (anticonvulsant drugs, metabolic acidosis without hypophosphatemia, pseudohypoparathyroidism, and chronic renal failure) have not demonstrated accumulation of osteoid due to delayed mineralization and primarily represent secondary hyperparathyroidism. Patients with the nephrotic syndrome lose albumin and vitamin D metabolites in the urine, but their serum ionized calcium and PTH levels are normal and metabolic bone disease in adults with the nephrotic syndrome is absent unless glucocorticoids have been administered.

CLINICAL MANIFESTATIONS

The clinical presentation of osteomalacia depends on three overlapping manifestations: those due to the underlying disorder such as gastrointestinal disease or surgery (especially troublesome are gastric resection, or gastric bypass for obesity [Chapter 201], celiac disease [Chapter 126], and intestinal malabsorption [Chapter 126]); those due to hypocalcemia or hypophosphatemia; and those directly due to the bone disease.

The most common symptoms and signs are pain in the pelvis and legs, muscle weakness, and bone tenderness. Bone pain is usually nonspecific and poorly localized. Because of the paucity of findings, the pains are often attributed to rheumatism or neurosis. Bone pain may be worse at night and after sudden movements, such as turning in bed or the change from sitting to standing.

The pain is worse on weight bearing, thereby resulting in a characteristic flat-footed, springless, waddling gait made worse by proximal muscle weakness. The gait has been referred to as "mother penguin's walk." Patients may complain that they can climb stairs only by pulling themselves up with the hand rail or rise from a chair or the toilet by using their hands to push off. The decrease in strength is usually far greater than the degree of muscle wasting.

Fasciculations are absent, and both reflexes and sensation remain normal. The bulbar, facial, and ocular muscles are always spared.

In X-linked hypophosphatemia, the family history is positive, and the typical presentation is short stature with lower extremity bowing. Muscle weakness is conspicuously mild or absent when the osteomalacia is due to X-linked hypophosphatemia.

Autosomal dominant hypophosphatemic rickets is characterized by a positive family history, spontaneous remissions, rather abrupt onset of profound fatigue and weakness, fractures, bone pain, and recurrent dental abscesses. This disorder may be triggered by iron deficiency from menorrhagia, nosebleeds, or pregnancy.

Hypocalcemia is usually mild to moderate but rarely can be severe enough to present with fingertip paresthesias, muscle cramps, or seizures, especially in patients with epilepsy. If the osteomalacia is mistaken for osteoporosis and treatment is started with a bisphosphonate or denosumab, the patient may experience new-onset paresthesias, muscle cramps, and palpitations. This not uncommon scenario occurs because the antiresorptive treatment interferes with the mobilization of calcium from bone by parathyroid hormone (PTH), thereby aggravating the hypocalcemia. The secondary hyperparathyroidism will also worsen the hypophosphatemia by the effect of PTH on renal excretion at the same time that intestinal absorption is impaired and mobilization from bone is blocked.

DIAGNOSIS

In osteomalacia, bone tenderness often can be elicited by rib cage compression or pressing on the tibiae, wrists, pubic rami, or iliac crests. If hypocalcemia is severe, patients may have a positive Chvostek (a facial twitch provoked by a gentle facial tap in front of the ear) or Trousseau sign (carpopedal spasm provoked by inflating a blood pressure cuff).

Biochemical changes depend on the stage of the disease and its etiology. In vitamin D deficiency, hypophosphatemia precedes and is more severe than the hypocalcemia because of the secondary hyperparathyroidism (Chapter 227) that usually accompanies the disorder by the time that osteomalacia has occurred. However, it remains unclear why some patients do not demonstrate increased PTH levels when severely vitamin D deficient. In malabsorption, hypomagnesemia may contribute to the hypocalcemia by impairing PTH secretion, and hypoalbuminemia may lead to a spurious diagnosis of hypocalcemia. Increased serum alkaline phosphatase activity is classically associated with osteomalacia due to vitamin D deficiency but usually is not an early clue. The serum 25-hydroxyvitamin D levels are often less than 10 to 15 ng/mL. In contrast, serum 1,25-dihydroxyvitamin D levels are usually elevated owing to the concomitant secondary hyperparathyroidism and usually do not contribute to the diagnosis of osteomalacia. However, in the rare autosomal recessive condition of a defective vitamin D receptor (vitamin D–dependent rickets type II), serum 1,25-dihydroxyvitamin D and PTH levels may be extraordinarily high (see Table 226-1). This condition is characterized by consanguinity, alopecia, and early-onset hypocalcemia. In another rare autosomal recessive disorder with defective 1α-hydroxylation of 25-hydroxyvitamin D (vitamin D–dependent rickets type I), serum 1,25-dihydroxyvitamin D levels may be undetectable. This disorder also is characterized by consanguinity and early-onset hypocalcemia. Quite a different pattern occurs with the inherited disease hypophosphatasia: serum 25-hydroxyvitamin D and calcium are normal, phosphorus is high-normal or slightly elevated, and alkaline phosphatase activity is below the normal age-matched range. This disease is caused by a deficiency of the tissue-nonspecific (liver, bone, and

FIGURE 226-2. Radiographic evidence of a pseudofracture of the femoral neck is suspicious for osteomalacia (*arrow*).

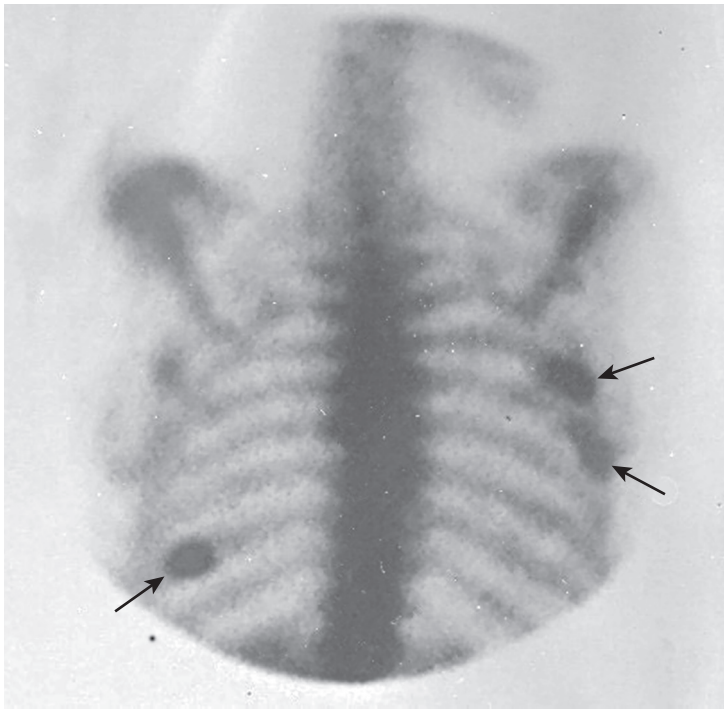

FIGURE 226-3. In osteomalacia, focal increased uptake of radionuclide on a bone scan may erroneously suggest metastatic disease (*arrows*).

kidney) isoenzyme of alkaline phosphatase, which normally prevents extracellular accumulation of inorganic pyrophosphate. If alkaline phosphatase activity is deficient and inorganic pyrophosphate collects adjacent to bone, mineralization is inhibited. The adult form hypophosphatasia may present with mild or severe osteomalacia (the prevalence is 1:100,000 to 300,000). Elevated serum vitamin B_6 is a useful marker if supplements are stopped for about 1 week before testing. Calcium pyrophosphate dihydrate crystal deposition disease (chondrocalcinosis [Chapter 252]) occurs in about 25% of affected patients.

Tumor-induced osteomalacia merits consideration in adults who present with hypophosphatemia, few or no deformities, and no family history of skeletal disease.[8] However, if the family history is vague or absent, autosomal dominant hypophosphatemic rickets can masquerade as tumor-induced osteomalacia, but serum FGF-23 levels are generally much higher in tumor-induced osteomalacia than in X-linked hypophosphatemia or autosomal dominant hypophosphatemic rickets. Included in the differential diagnosis is Fanconi syndrome, but in this disease, the hypophosphatemia is accompanied by hypokalemia, glycosuria, and hyperchloremic acidosis.

Radiology

In any form of osteomalacia, radiographic findings may be subtle or absent, and only blurred margins of the cancellous bone with thin cortices may be noted. The presence of bilaterally symmetrical, thin (2 to 3 mm) radiolucent bands known as pseudofractures (Fig. 226-2) found perpendicular to the periosteal surface in ribs, pubic and ischial rami, neck of the femur, metatarsals, and below the glenoid fossa on the outer border of the scapulae is generally considered to be pathognomonic of osteomalacia. However, this radiographic finding may be seen in disorders lacking excessive osteoid. Distinguishing features of pseudofractures in osteomalacia are the lack of callus or adjacent sclerosis and absence of an inciting event. Usually, there are at least two or three of these fractures with at least one in the rib, pubic rami, or femora, and biochemical clues (hypocalcemia and hypophosphatemia) are present. If what appears to be a pseudofracture is accompanied by normal levels of serum calcium, phosphorus, and alkaline phosphatase activity, osteomalacia is unlikely.

Pseudofractures show increased uptake on bone scans (Fig. 226-3) and may lead to an inappropriate search for a malignancy. Pseudofractures are typically located in the medial cortex of long bones and must be distinguished from atypical femoral fractures, which are located in the lateral cortex with cortical thickening and a cortical beak. Both may occur in patients receiving treatment with bisphosphonates. Subtrochanteric femoral pseudofractures also may occur in the lateral cortex in hypophosphatasia. In Paget disease (Chapter 228), cortical stress or fissure fractures may resemble pseudofractures but have a predilection for the anterior aspects of a bowed femur or tibia. In contrast to osteomalacia, the surrounding bone has a distinctly abnormal radiographic appearance. In osteomalacia, bone mineral density T-scores are often −3 or −4, with the radial diaphyseal density T-scores lower than those of the lumbar spine and total proximal femur. Bone mineral density examination of the radial diaphysis allows a unique view of non–weight bearing, appendicular, cortical bone and may be the first clue to vitamin D deficiency osteomalacia.

When the knees are involved and magnetic resonance imaging (MRI) reveals an increased T2 signal, osteomalacia can be mistaken for a stress fracture or spontaneous osteonecrosis of the knee. A check of the serum 25-hydroxyvitamin D and alkaline phosphatase levels will reveal the correct diagnosis.

The mesenchymal tumors that cause tumor-induced osteomalacia are best localized using Ga-68 DOTA-somatostatin receptor (SSTR) positron emission tomography/computed tomography (PET/CT).[6] The sensitivity of this approach for finding the offending tumor is about 85%.

Celiac Diseases

Iron deficiency anemia, hypocalcemia, weight loss, glossitis or rash, and bone discomfort in a patient with low bone mineral density point to malabsorption or celiac disease (Chapter 126), even without gastrointestinal symptoms. Patients also may have persistently low serum 25-hydroxyvitamin D levels despite high-dose vitamin D supplementation. This scenario suggests the need to test for antiendomysial immunoglobulin A and tissue transglutaminase antibodies.

Differential Diagnosis

Although characteristic clinical, radiographic, and biochemical findings may suggest osteomalacia, the absence of these findings cannot exclude the diagnosis. Bone biopsy is needed to establish the unequivocal presence of osteomalacia (see Fig. 226-1). However, bone biopsy is rarely necessary unless the patient has unusually painful disease or progressive loss of bone density and the results of the physical examination, radiographs, and biochemical findings are ambiguous. When biopsy is necessary, the best solution is to refer the patient to a bone histomorphometry center.

Unexplained elevations of the serum alkaline phosphatase activity (Chapter 133) are usually due to drugs (e.g., anticonvulsants, anabolic steroids, phenothiazines, or antibiotics) or Paget disease of bone (Chapter 228). These possibilities may be distinguished by measurement of the serum bone alkaline phosphatase by immunoassay, although there is up to 15 to 20% cross-reactivity with hepatic alkaline phosphatase. Isoenzyme determination by heat fractionation is not helpful. However, increased serum alkaline phosphatase activity is rarely the only biochemical clue to osteomalacia in a patient with skeletal discomfort. A nuclear medicine bone scan may be useful in difficult cases.

TREATMENT

The treatment of osteomalacia depends on its cause. Most osteomalacia is due to disorders of the absorption or metabolism of vitamin D or to chronic hypophosphatemia, and the remainder of cases are due to inhibitors of mineralization.

Osteomalacia Due to Vitamin D Disorders

Patients with severe disease require vitamin D and calcium supplementation.[7] A loading dose accelerates recovery and depends on the serum 25-hydroxyvitamin D level (Table 226-2). Although vitamin D_3 supplementation may be somewhat more potent than with D_2, the differences are not clinically important with the doses recommended for osteomalacia. The goal is to raise the serum 25-hydroxyvitamin D level to well above 30 ng/mL and reduce the elevated PTH concentration to normal without hypercalcemia or hypercalciuria. Pharmacologic doses of any vitamin D preparation carry the risk for vitamin D intoxication, so increases in the dose must be made carefully. However, the doses recommended in Table 226-2 will rarely result in serum 25-hydroxyvitamin D levels of 80 to 100 ng/mL, and vitamin D intoxication is unlikely even with levels of 150 ng/mL.

Approximately 1 to 1.5 g per day of oral elemental calcium is a reasonable initial dose depending on the degree of malabsorption (Table 226-3). Frequent small doses (three times a day) are more effective and tolerable than fewer larger ones, and the absorbability of calcium supplements is enhanced with meals. Urinary calcium excretion should be monitored after treatment has normalized the serum calcium level. The urinary calcium-to-creatinine ratio (mg/mg) should be kept below 0.22.

For malabsorption and celiac disease (Chapter 126), advice on nutrition and sun exposure, discontinuation of offending drugs, adherence to a gluten-free diet, and pancreatic enzyme replacement may cure the mineralization defect in some patients with mild celiac disease without the need for additional treatment. In patients with malabsorption, vitamin D requirements may rise during periods of increased diarrhea, and calcitriol may be easier for these patients to absorb. Its rapid onset of action and disappearance after cessation add to the safety of treatment, albeit at greater cost (see Table 226-2). Use of calcitriol requires great care to avoid hypercalcemia and hypercalciuria. Calcium, phosphorus, potassium, magnesium, and multivitamins also may be beneficial in patients with malabsorption (Table 226-4; see Table 226-3).

Rare patients do not tolerate any form of oral vitamin D, and the parenteral calciferol preparations available in North America are ineffective. These patients can be improved, although not restored to normal, by the use of weekly tanning bed treatments to areas of their bodies not normally exposed to the sun, with an attempt to minimize risk for solar-induced skin cancer (Chapter 188).

Calcitriol is the drug of choice in patients with vitamin D–dependent rickets type I. In patients with vitamin D–dependent rickets type II and diminished receptor sensitivity to 1,25-dihydroxyvitamin D, extraordinarily high doses of calcitriol may partially overcome the defect. If oral treatment fails, nocturnal infusions of calcium and phosphorus have been successful, thereby providing additional evidence that the osteomalacia is due to inadequate calcium and phosphorus rather than from the defect in vitamin D metabolism.

An increase in the serum alkaline phosphatase activity (the healing "flare") and a small increase in the serum and urine calcium levels are the earliest signs of effective treatment. Thereafter, the serum alkaline phosphatase activity level progressively falls as healing occurs. At the start of therapy, serum calcium levels should be measured every 2 to 3 weeks. If hypoalbuminemia is present, serum ionized calcium determinations or albumin-adjusted calcium values are useful. When therapy appears stabilized, repeat determinations at 6- to 8-week intervals are usually sufficient, but measurements should be at least three times a year even with long-term therapy. In some patients with severe osteomalacia, bone pain and paresthesias may increase and the serum calcium levels decrease during the first few weeks of therapy. This phenomenon is due to the increased skeletal avidity for mineral during healing and indicates the need for additional calcium supplementation.

Osteomalacia Due to Hypophosphatemia

Therapy of chronic hypophosphatemia is aimed at maintaining normal concentrations of serum phosphorus without inducing secondary hyperparathyroidism or hypercalciuria.[8] This considerably difficult task requires divided doses of phosphorus supplements and calcitriol to increase the absorption of phosphorus and calcium as well as to prevent the resultant increase in PTH. Regrettably, this regimen is often poorly tolerated, with side effects including diarrhea, secondary or tertiary hyperparathyroidism, nephrocalcinosis,

TABLE 226-2 VITAMIN D PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

	VITAMIN D_2 (ERGOCALCIFEROL)	VITAMIN D_3 (CHOLECALCIFEROL)	CALCITRIOL† [1,25(OH)$_2$D$_3$]
Trade name	Drisdol and others*	Bio-Tech D3-50	Rocaltrol
Dosage form	Caps: 50,000 U = 1.25 mg	Caps: 50,000 U = 1.25 mg	Caps: 0.25 and 0.50 µg
Loading dosage:			
If 25(OH)D = 20-30 ng/mL	50,000 U once/wk for 10 wk‡ and once/mo thereafter (or 2000 U/day)	50,000 U once/wk for 10 wk‡ and once/mo thereafter (or 2000 U/day)	
If 25(OH)D = 10-20 ng/mL	50,000 U twice/wk for 10 wk‡ and twice/mo thereafter	50,000 U twice/wk for 10 wk‡ and twice/mo thereafter	
If 25(OH)D = <10 ng/mL	50,000 U three times/wk for 10 wk‡ and three times/mo thereafter	50,000 U three times/wk for 10 wk‡ and three times/mo thereafter	
Dosage in resistant cases	Up to 50,000 U/day	Up to 50,000 U/day	2-8 µg/day
Time to reach maximal effects	4-10 wk	4-10 wk	3-7 days
Persistence of effects after cessation	6-30 wk	6-30 wk	3-4 days
Cost	$203/100 gel caps Noncompliance may occur if the patient's insurance and pharmacy dispense only a 3-month supply and charge a large co-payment. These problems are avoided with Bio-Tech D3-50.	$28/100 capsules	$130/100 generic calcitriol capsules of 0.25 µg $200/100 generic calcitriol capsules of 0.5 µg $180/15 mL (1 µg/mL) generic calcitriol oral solution

*Gel caps are best because hard capsules may be indigestible and unreliable.

†Calcitriol is reserved for patients with persistent elevation of parathyroid hormone despite normalization of the serum 25-hydroxyvitamin D level. Hypercalcemia and hypercalciuria must be avoided.

‡If not >30 ng/mL after 10 weeks, exclude malabsorption, celiac disease, and noncompliance. Weekly tanning bed treatments may be used if oral vitamin therapy fails, or a switch to the more costly calcitriol may be necessary.

TABLE 226-3 CALCIUM PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

PREPARATION	PERCENT ELEMENTAL CALCIUM	AMOUNT OF ELEMENTAL CALCIUM IN THE SUGGESTED DOSE	COST PER MONTH OF THERAPY
Calcium carbonate 600 mg tablets	40	4 tabs = 960 mg	$8
TUMS Ultra 1000 mg (chewable)	40	2 tabs = 800 mg	$8
Citracal Slow Release 1200 mg (85% calcium carbonate and 15% calcium citrate) plus 1000 units vitamin D		4 tabs = 892 mg	$9
Viactiv Chews (chocolate, caramel, or mocha) 650 mg calcium and 500 units vitamin D		2 chews = 1300 mg	$10

K-Phos No 2	250	5.8	2.3	4 tabs	$99/100 tablets

*Each unit dose cap is reconstituted with at least 75 mL of water, fruit juice, or cola. The unit dose cap or packet contains the powder concentrate and is not to be swallowed undiluted. The powder preparations cost less and may be the only phosphate preparation covered by some insurance plans.

or nephrolithiasis. Therefore, a calcitriol-alone regimen should be first using about 0.25 to 0.5 µg of calcitriol once or twice daily while monitoring for hypercalciuria. Phosphate supplements (no more than 250 mg of elemental phosphorus four times daily and advanced slowly with repeat levels within 3 to 4 weeks) should be delayed until calcitriol alone has been used for several weeks without significantly increasing the serum phosphorus. If the serum phosphorus level has not changed or decreased and the PTH level has increased, the calcitriol dose rather than the phosphorus dose should be advanced to avoid secondary hyperparathyroidism (Chapter 227). Baseline and yearly renal ultrasound examinations are necessary to assess early nephrocalcinosis or nephrolithiasis. Burosumab is an FGF-23 antibody that can sustain normal levels of serum phosphorus far more effectively than treatment with phosphate and calcitriol. However, its high price generally restricts insurance coverage to patients who have genetic verification of X-linked hypophosphatemia and have failed to normalize their serum phosphorus levels with calcitriol and phosphate without developing hypercalciuria. Burosumab (1 mg/kg up to 90mg injected subcutaneously every 4 weeks with monitoring of the phosphorus and calcium levels two weeks after injection for the first few months) increases healing of fractures and improves exercise capacity, often with resultant weight loss.[A1] Treatment is lifelong. Restless leg syndrome is a possible adverse effect.

In hypophosphatasia, treatment with teriparatide (20 µg every other day) can increase bone density and repair of fractures.[9] Bone-targeted enzyme replacement therapy (asfotase alfa; 2 mg/kg three times a week) is also effective,[10] but its very high price generally restricts insurance coverage to patients with juvenile onset disease and failure to increase alkaline phosphatase activity with teriparatide.

Surveillance is required for injection site reactions and corneal calcifications. General measures remain important and include routine nutritional advice and avoidance of further bone loss due to vitamin D deficiency. High-dose vitamin D therapy in hypophosphatasia can cause nephrocalcinosis, nephrolithiasis, and renal insufficiency and should be avoided.

Tumor-induced osteomalacia can be treated with phosphorus supplementation and calcitriol, but burosumab (usually 1 mg/kg up to 90 mg subcutaneously every 4 weeks) restores phosphorus homeostasis and ambulatory status more efficiently and is recommended, despite its price, when phosphorus and calcitriol are insufficient.[11,12] Complete resection of the tumor results in cure of the osteomalacia, but offending tumors can be hard to find and difficult to remove completely.

PREVENTION

Nutritional rickets and osteomalacia are common in dark-skinned and migrant populations, and their global incidence is rising because of changing population demographics, failing prevention policies, and inadequate implementation strategies. High-risk populations require lifelong supplementation and food fortification with vitamin D or calcium. Advice about vitamin D supplementation should help to prevent osteomalacia caused by vitamin D deficiency, but routine over-the-counter supplements may be insufficient or ineffective, and compliance with nutritional supplements is poor. The optimal vitamin D supplementation dosage is not clear, but most bone and mineral problems are avoided by 50,000 U of cholecalciferol given once monthly (or, 1600 to 2000 U/day). Notable exceptions occur in patients who have celiac disease or who have had gastric surgery or bypass for obesity; these patients often require much higher doses (see Table 226-2). In patients with osteomalacia due to hypophosphatemia, the need for phosphorus supplementation may be lifelong (see Table 226-4).

PROGNOSIS

The response to appropriate treatment in most forms of osteomalacia is usually excellent. Improvements in bone pain and muscle weakness usually occur within 2 or 3 months, and skeletal lesions usually heal within 6 to 18 months. Depending on the quantity of excess osteoid, repeat bone mineral density determinations may show as much as 20% gains at the lumbar spine and total proximal femur. However, bone density at the radial diaphysis may not improve owing to the irreversible loss of cortical bone resulting from prolonged secondary hyperparathyroidism.

227 THE PARATHYROID GLANDS, HYPERCALCEMIA, AND HYPOCALCEMIA

RAJESH V. THAKKER

CALCIUM METABOLISM

A healthy adult body has a total of 1 kg of calcium, about 99% of which is within the crystal structure of bone mineral and less than 1% of which is in soluble form in the extracellular and intracellular fluid compartments. In the extracellular fluid compartment, about half of the total calcium is ionized, and the remainder is principally bound to albumin or complexed with counter-ions. Ionized calcium in the extracellular fluid plays an important role in many physiologic pathways, including muscle contraction, secretion of neurotransmitters and hormones, and coagulation pathways. The total serum calcium concentration ranges from 8.5 to 10.5 mg/dL (2.12 to 2.62 mmol/L), whereas ionized serum calcium concentrations range from 4.65 to 5.25 mg/dL (1.16 to 1.31 mmol/L).[1] However, the usual 2 : 1 ratio of total to ionized calcium may be disturbed by disorders such as metabolic acidosis (Chapter 104), which reduces calcium binding by proteins, or by changes in protein concentration, caused by cirrhosis (Chapter 139), dehydration, venous stasis (Chapter 68), or multiple myeloma (Chapter 167). As a result, the total serum calcium concentrations may need to be adjusted, or "corrected," to a reference albumin concentration by adding or subtracting 0.8 mg/dL (0.016 mmol/L) for every 1 g/dL (1 g/L) of albumin below or above the reference albumin concentration of 4 g/dL.

The control of body calcium involves a balance between the amounts that are absorbed from the gut, deposited into bone and into cells, and excreted from the kidney (Fig. 227-1). This fine balance, which involves three organs, is chiefly under the control of parathyroid hormone (PTH), which is synthesized and secreted by the parathyroid glands. Hypocalcemia leads to an increased secretion of PTH, whereas hypercalcemia results in diminished secretion of PTH. Regulation of extracellular calcium takes place through complex interactions (E-Fig. 227-1) at the target organs of the major calcium-regulating hormone, PTH, and vitamin D and its active metabolites, 1,25-dihydroxyvitamin D ($1,25[OH]_2D$), which is also referred to as calcitriol.[2]

PARATHYROID GLANDS AND PARATHYROID HORMONE

Humans usually have four parathyroid glands, which are located in close proximity to the superior and inferior poles of the lobes of the thyroid gland. The superior parathyroids are derived from the endoderm of the embryonic fourth pharyngeal pouches, and the inferior parathyroids are derived with the thymus from the endoderm of the third pharyngeal pouches. Extra parathyroid glands, which may be present in 3 to 5% of the population, are commonly found in aberrant locations along this migrating path and also within the thymus and thyroid.

Parathyroid cells express a G protein–coupled receptor (GPCR), referred to as the calcium-sensing receptor, that detects changes in extracellular calcium and leads to alterations in the secretions of PTH.[3] For example, activation of the calcium-sensing receptor, which is also expressed in renal tubular cells as a result of elevated extracellular calcium concentrations, causes G protein–dependent stimulation of phospholipase C activity, which in turn leads to accumulation of inositol 1,4,5-trisphosphate and an increase in intracellular calcium concentrations. These changes then lead to reduced circulating concentrations of PTH and increased urinary excretion of calcium. Disorders of the parathyroid glands may cause hypercalcemia or hypocalcemia, which can be classified according to whether they arise from an excess of PTH, its deficiency, or insensitivity to its effects (Table 227-1; see E-Fig. 227-1).

In chronic renal insufficiency, uremia (Chapter 116) with low serum calcium levels and elevations in serum phosphate levels, secretion of PTH increases. This physiologic secondary hyperparathyroidism in response to hypocalcemia can progress to become an independent parathyroid adenoma—defined as tertiary hyperparathyroidism (see Chronic Hyperparathyroidism).

Parathyroid Hormone and *PTH* Gene

PTH is an 84–amino acid peptide encoded by the *PTH* gene, which is located on chromosome 11p15. The mature PTH peptide is secreted from

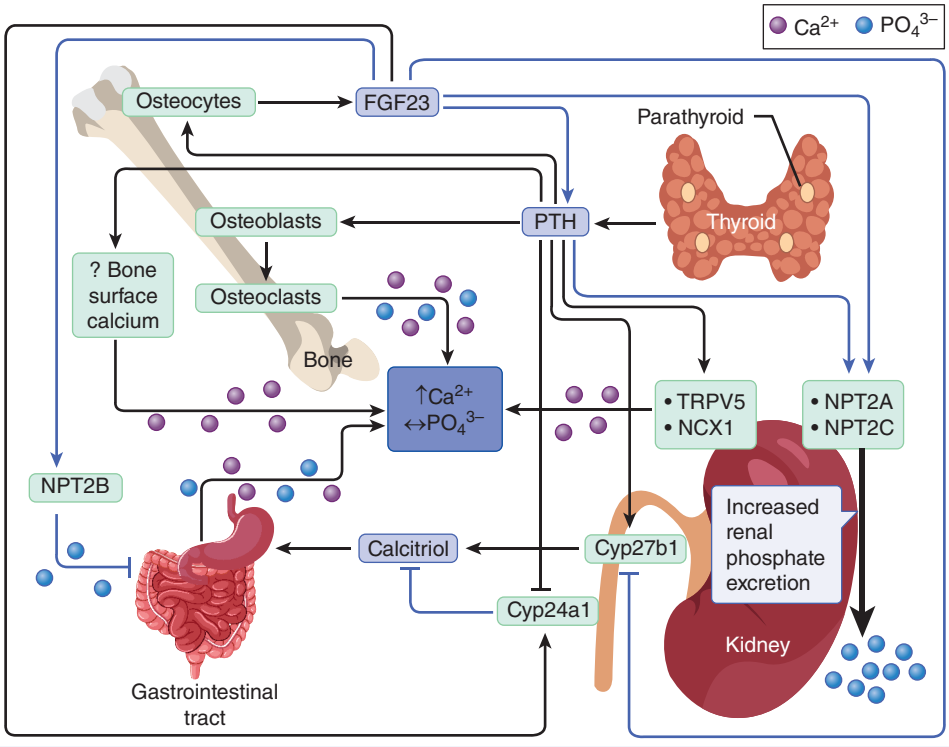

FIGURE 227-1. Regulation of calcium and phosphate economy and bone mass. The secretion of parathyroid hormone (PTH) from the parathyroid glands increases in response to low serum concentrations of calcium (Ca^{2+}). Within bone cells, PTH stimulates osteoblasts to form bone, indirectly stimulates osteoclasts to resorb bone and bring calcium and phosphate (PO_4^{3-}) into the circulation, and acts on osteocytes to stimulate the release of fibroblast growth factor 23 (FGF23). Within kidney tubules, PTH increases reabsorption of calcium and renal excretion of phosphate, and FGF23 also stimulates renal phosphate excretion. FGF23 acts indirectly on the intestines by controlling the level of calcitriol, but might also have direct actions to regulate the expression of the sodium-phosphate co-transporter 2b (NPT2B). Within intestines, calcitriol increases intestinal calcium and phosphate absorption. The integration of these regulators includes that PTH increases the release of FGF23 and increases calcitriol levels, whereas FGF23 has opposing effects to inhibit PTH and decrease calcitriol. The central, *dark-blue box* indicates the circulating or blood concentrations of calcium and phosphate. The *question mark* indicates an unclear process. *Black arrows* indicate pathways with net stimulatory actions whereas *blue arrows* are pathways with net inhibitory action. *Flat arrowheads* indicate inhibitory actions. ABSTRACT

Calcium plays an important role in many physiologic pathways that include muscle contraction, the secretion of neurotransmitters and hormones, and coagulation. The control of body calcium involves a balance between the amounts that are absorbed from the gut, deposited into bone and cells, and excreted from the kidney. This fine balance, involving all these organs, is chiefly under the control of parathyroid hormone (PTH), which is synthesized and secreted by the parathyroid glands. Thus, hypocalcemia will lead to an increased secretion of PTH, whereas hypercalcemia will result in diminished secretion of PTH. Oversecretion of PTH due to parathyroid tumors is a major cause of hypercalcemia, which may be associated with kidney stones, osteoporosis, and peptic ulcers. PTH deficiency, which results in hypocalcemia, may be associated with epilepsy, tetany, cataracts, skeletal malformations, and abnormal dentition. This chapter reviews the genetic basis for disorders of calcium metabolism, the physiologic and biochemical mechanisms underlying extracellular calcium homeostasis, the clinical features of hypercalcemia and hypocalcemia, and the clinical disorders associated with abnormal calcium homeostasis, as well as the management of hypercalcemia and hypocalcemia.

E-FIGURE 227-1. Schematic representation of some of the components involved in calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (CaSR), which is a 1078–amino acid G protein–coupled receptor. The PTH/PTHrP receptor, which mediates the actions of PTH and PTHrP, is also a G protein–coupled receptor. Thus, Ca^{2+}, PTH, and PTHrP involve G protein–coupled signaling pathways, and interaction with their specific receptors can lead to activation of Gs, Gi, and Gq/α11, respectively. Gs stimulates adenylcyclase (AC), which catalyzes the formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). Gi inhibits AC activity. cAMP stimulates protein kinase A (PKA), which phosphorylates cell-specific substrates. Activation of Gq/α11 stimulates phospholipase C (PLC), which catalyzes the hydrolysis of the phosphoinositide (PIP_2) to inositol triphosphate (IP_3), which then increases intracellular calcium, and diacylglycerol (DAG), activating protein kinase C (PKC). These proximal signals modulate downstream pathways, which result in specific physiologic effects. Loss- and gain-of-function mutations in several genes, shown with their respective sites of action on the right, have been identified in specific disorders of calcium homeostasis (also see Table 227-1). (From Thakker RV, Bringhurst FR, Jüppner H. Regulation of calcium homeostasis and genetic disorders that affect calcium metabolism. the parathyroid chief cells as an 84–amino acid peptide; however, when the *PTH* mRNA is first translated, it is as pre-proPTH peptide. The "pre" sequence consists of a 25–amino acid signal peptide (leader sequence) that is responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell. The "pro" sequence is 6 amino acids in length and is also essential for correct processing and secretion of PTH. After the 84–amino acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation by nonsaturable hepatic uptake and renal excretion, with a short half-life of about 2 minutes.

Actions of Parathyroid Hormone

PTH and PTH-related peptide (PTHrP) share a GPCR (see E-Fig. 227-1), which predominantly is expressed in kidney and bone, where it enhances renal calcium reabsorption, releases stored calcium from bones into the extracellular fluid, and also acts indirectly on intestinal cells (see later) to increase calcium absorption in the gut. Expression of the PTH/PTHrP receptor also occurs in the brain, heart, skin, lung, liver, and testis, where it mediates the actions of PTHrP. Mutations involving the genes that encode these proteins and receptors in this calcium-regulating pathway (see E-Fig. 227-1) are associated with hypercalcemic and hypocalcemic disorders (see Table 227-1).

Renal Actions

Calcium is absorbed by the kidneys at multiple sites along the renal tubule and by different mechanisms, including passive paracellular or active transcellular transport. The renal actions of PTH are to: stimulate activity of the proximal tubular cell 1α-hydroxylase; increase reabsorption of calcium by the cells of the distal tubule, connecting tubules, and the thick ascending loop of Henle; and inhibit phosphate reabsorption by proximal tubular cells (see Fig. 227-1). PTH increases the formation of biologically active $1,25(OH)_2D$ from its precursor 25-OH-D by stimulating the activity of the renal 1α-hydroxylase and inhibiting the 24-hydroxylase, which metabolizes $1,25(OH)_2D$ to the inactive $24,25(OH)_2D$ form (see Fig. 227-1). PTH regulates calcium reabsorption by distal tubular cells by upregulating expression of the transient receptor potential vanilloid 5 (TRPV5), thereby promoting calcium entry into the cell and increasing calbindin-D28K expression to enhance transcellular calcium reabsorption by increased buffering of subapical Ca^{2+} ions. In the thick ascending loop of Henle, PTH may increase the active transcellular transport of calcium and the paracellular transport of calcium by augmenting the transepithelial voltage gradient. Phosphate transport in proximal tubular cells is mediated by the luminal membrane sodium-phosphate cotransporters 2a and 2c (NPT2a and NPT2c), and PTH actions lead to internalization and degradation of NPT2a and NPT2c, thereby resulting in decreased reabsorption of phosphate.

Skeletal Actions

PTH acts directly on osteoblasts and indirectly on osteoclasts to increase their numbers and activity, thereby enhancing bone turnover and the release of stored calcium. PTH increases the size of the osteoblast precursor pool, increases the bone-forming activity of mature osteoblasts, and stimulates osteoblasts to release cytokines such as colony-stimulating factor 1 and receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), which stimulate the formation of new osteoclasts and activate mature osteoclasts. PTH also inhibits the production of osteoprotegerin, which is a decoy receptor that binds to RANKL and thereby inhibits the development of osteoblasts. The net result of persistent elevations of PTH is an increase in osteoclast activity more than osteoblast activity, thereby liberating the stores of calcium from bone into the extracellular fluid (see Fig. 227-1).

Intestinal Actions

Calcium is absorbed throughout the intestine by passive paracellular routes and active transcellular routes. PTH exerts indirect actions on intestinal calcium absorption by increasing the circulating $1,25(OH)_2D$ concentrations (see Fig. 227-1). The increased $1,25(OH)_2D$ concentrations facilitate enhanced calcium entry into the cell from the lumen, thereby facilitating transcellular transport of calcium.

HYPERCALCEMIA

DEFINITION

Hypercalcemia is defined as a serum calcium concentration greater than 2 standard deviations above the normal mean, which is usually a total serum calcium above 10.5 mg/dL (2.62 mmol/L) and an ionized serum calcium of above 5.25 mg/dL (1.31 mmol/L). No formal grading system defines the severity of hypercalcemia, but mild, moderate, and severe hypercalcemia are generally considered for total serum calcium concentrations less than 12 mg/dL (3 mmol/L), between 12 and 14 mg/dL (3 to 3.5 mmol/L), and greater than 14 mg/dL (3.50 mmol/L), respectively.

EPIDEMIOLOGY

The prevalence of hypercalcemia has been reported as 1% to 2% in the general population and about 2 to 5% in hospitalized patients.

PATHOBIOLOGY

Hypercalcemia may arise through one of three mechanisms: increased bone resorption, increased gastrointestinal absorption of calcium, and decreased renal calcium excretion (see Fig. 227-1). For example, lytic bone metastases cause increased bone resorption; thiazide diuretics lead to a decrease in calcium excretion; and excessive PTH will either directly or indirectly increase the production of $1,25(OH)_2D$ and stimulate bone resorption and calcium absorption from the gut and renal tubules. The causes of hypercalcemia may be classified according to whether serum PTH concentrations are elevated (i.e., primary or tertiary hyperparathyroidism due to parathyroid tumors) or reduced (i.e., not due to parathyroid tumors but instead to an excessive production of PTHrP by lytic bone metastases, multiple myeloma, drugs, or an altered set point in the calcium-sensing receptor[4]; see E-Fig. 227-1). In secondary hyperparathyroidism, by comparison, PTH levels are increased in response to a low serum calcium level (usually due to chronic renal failure or vitamin D deficiency) and, by definition, the patient cannot have hypercalcemia.

TABLE 227-2 CLINICAL FEATURES OF HYPERCALCEMIA

Renal
Stones (nephrolithiasis) and nephrocalcinosis, polyuria, polydipsia
Musculoskeletal
Bone pain, osteopenia, fractures, muscular weakness, especially proximal myopathy
Gastrointestinal
Nausea, vomiting, lack of appetite, constipation, peptic ulcers, and pancreatitis
Neurologic
Tiredness, lethargy, inability to concentrate, increased sleepiness, depression, confusion, coma
Cardiac
Bradycardia, first-degree atrioventricular block, arrhythmias, shortened QT interval

CLINICAL MANIFESTATIONS

In developed countries, the clinical presentation of hypercalcemia is most commonly as an asymptomatic, biochemical abnormality detected during routine screening. However, it also can present as a life-threatening medical emergency, especially in developing countries and in patients with cancer (Chapter 164). In general, the presence or absence of symptoms correlates with the severity of the hypercalcemia. Symptoms do not usually develop when serum calcium is below 12 mg/dL (3 mmol/L) and are nearly invariably present when the hypercalcemia exceeds 14 mg/dL (3.5 mmol/L). However, there is considerable variability, in part dependent on the rapidity of onset of mild to moderate hypercalcemia. The signs and symptoms of hypercalcemia (Table 227-2) are similar, regardless of etiology. The clinical manifestations can involve the renal, musculoskeletal, gastrointestinal, neurologic, and cardiac systems, and many of these have been referred to as "moans, groans, pains, and stones."

DIAGNOSIS

Investigations should be directed at confirming the presence of hypercalcemia and establishing the cause (Fig. 227-2). Hypercalcemia can be caused by a number of conditions (Table 227-3, and a careful initial evaluation (Table 227-4) is key. Primary hyperparathyroidism and malignancy, which are the most common causes,[5] account for more than 90% of patients with hypercalcemia. Detailed clinical history and examination will usually help to differentiate between these two diagnoses. In primary hyperparathyroidism, the hypercalcemia is often less than 12 mg/dL (3 mmol/L), asymptomatic, and may have been present for months or years. If symptoms, such as nephrolithiasis (Chapter 111), are noted, then hypercalcemia usually has been present for at least several months. In malignancy, however, patients are usually acutely ill, often with neurologic symptoms; the hypercalcemia is more than 12 mg/dL (3 mmol/L), and the cancer (e.g., lung, breast, or myeloma) is often readily apparent. If bone metastases or chronic renal failure are the cause, the serum phosphate level is typically elevated, whereas it is normal or low when the PTH level is elevated. Hypercalcemia from other causes is usually suggested by a careful history (e.g., for vitamin D ingestion, drugs, renal disease) and physical examination (e.g., for thyrotoxicosis, adrenal disease, granulomatous diseases). However, appropriate laboratory investigations (see Table 227-4 and Fig. 227-2), are essential for establishing the diagnosis.[6]

TREATMENT

The treatment of hypercalcemia depends on the severity of the hypercalcemia and the presence of symptoms. Asymptomatic patients with mild hypercalcemia do not usually need urgent treatment, patients with severe hypercalcemia require treatment regardless of symptoms, and patients with moderate hypercalcemia require urgent treatment if symptomatic.

Before instituting treatment, it is always important to consider the underlying causes (see Table 227-3) and to initiate investigations (see Table 227-4). In addition, drugs such as thiazides and vitamin D compounds, which cause hypercalcemia, should be discontinued and dietary calcium intake should be restricted.

Symptomatic Hypercalcemia

Dehydration owing to hypercalcemic symptoms (e.g., anorexia, nausea, vomiting, and polyuria because of defective urinary concentration) is very common, so the acute management of symptomatic hypercalcemia involves hydration and calcium diuresis, as well as specific measures using drugs to lower the serum calcium level. Saline, which enhances urinary calcium excretion by increasing glomerular filtration and reducing the proximal and distal renal tubular reabsorption of calcium and sodium, is given as required (5 to 10 L of 0.9% sodium

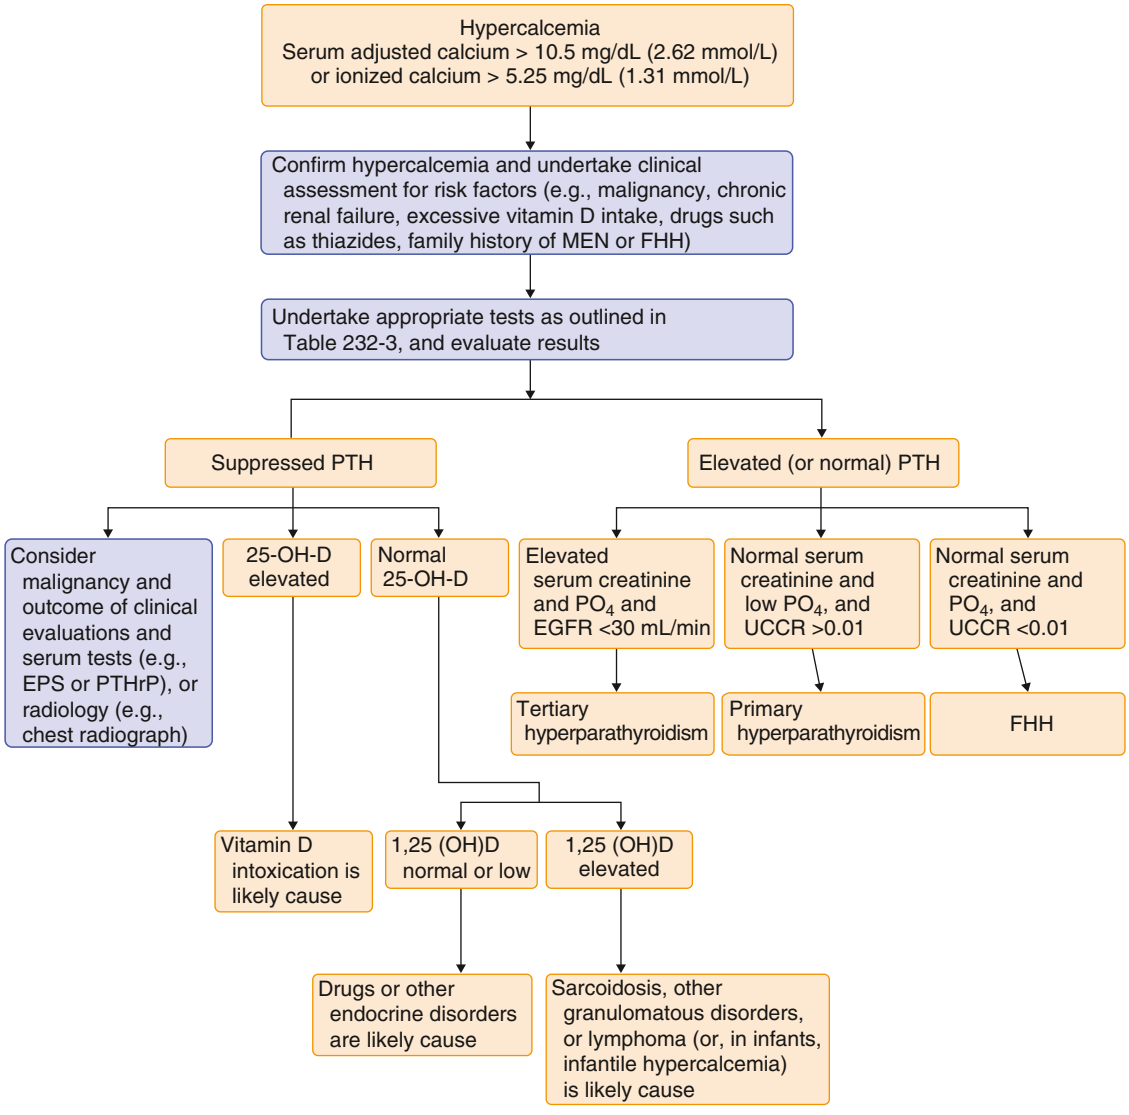

FIGURE 227-2. Clinical approach to the investigation of causes of hypercalcemia. 1,25(OH)$_2$D = 1,25-dihyroxyvitamin D; 25-OH-D = 25-hydroxyvitamin D; EGFR = estimated glomerular filtration rate; EPS = electrophoretic strip (serum protein electrophoresis); FHH = familial hypocalciuric hypercalcemia; MEN = multiple endocrine neoplasia; PTH = parathyroid hormone; PTHrP = parathyroid hormone–related peptide; UCCR = 24-hour urinary calcium clearance-to-creatinine clearance ratio.

chloride over a 24- to 48-hour period). This vigorous saline hydration, which may lower serum calcium by 1 to 3 mg/dL (0.25 to 0.75 mmol/L), may need to be combined with a loop diuretic (e.g., furosemide, 10 to 20 mg) as necessary to avoid or control complications due to volume overload, especially in elderly patients and patients who have impaired cardiovascular and renal function. The furosemide must be used carefully to avoid exacerbating volume depletion, thereby worsening the hypercalcemia. Saline diuresis may lead to hypokalemia, hypomagnesemia, and electrolyte imbalance, so these parameters must be monitored and corrected as needed.

If saline diuresis is not successful, particularly if the hypercalcemia is very severe, then more specific drugs will be required. The drugs of choice are zoledronic acid (4 mg as a single IV infusion) or pamidronate (15 to 60 mg, depending on the serum calcium concentration, in a single IV infusion or in divided doses, depending upon renal function and responses, over 2 to 4 days; maximum of 90 mg per treatment course). However, these agents should not be used if the hypercalcemia is due to primary or tertiary hyperparathyroidism; such patients ideally should be referred for surgical removal of their parathyroid tumors. Glucocorticoid therapy (e.g., hydrocortisone, 120 mg/day in three divided doses, in adults) is particularly effective when the hypercalcemia is mediated by the actions of 1,25(OH)$_2$D, for example in granulomatous disease, lymphoma, or myeloma. Dialysis using a low or zero calcium dialysate should be considered if these treatments are not effective or if the patient has renal failure. When the acute management of hypercalcemia has been completed, appropriate treatment for the underlying cause must be undertaken.

SPECIFIC CAUSES OF HYPERCALCEMIA

HYPERPARATHYROIDISM

DEFINITION

Hyperparathyroidism, which is characterized by high concentrations of serum immunoreactive PTH, can be classified as primary, secondary, or tertiary. Primary and tertiary hyperparathyroidism are essentially always associated with hypercalcemia (see Table 227-3). By comparison, secondary hyperparathyroidism, which is a physiological response to hypocalcemia, by definition is not associated with hypercalcemia; it may resolve when the hypocalcemia is corrected, or it may progress to tertiary hyperparathyroidism, which usually arises in association with chronic renal failure (see later).

A normocalcemic form of primary hyperparathyroidism is characterized by a normal serum calcium concentration in association with an elevated intact PTH level on at least two consecutive occasions over 3 to 6 months in the absence of any cause of secondary hyperparathyroidism.[7] The prevalence of normocalcemic hyperparathyroidism is reported to be less than 0.2% among persons who undergo assessment of bone mineral density. The serum calcium level may remain normal, or this condition may sometimes be a prelude to the development of primary hyperparathyroidism.

Primary hyperparathyroidism usually occurs as an isolated nonsyndromic endocrinopathy and less commonly as part of complex syndromic disorders such as multiple endocrine neoplasia (MEN; Chapter 212) and

TABLE 227-3 CAUSES OF HYPERCALCEMIA

HIGH PARATHYROID HORMONE LEVELS
Primary hyperparathyroidism* (adenoma, hyperplasia, or carcinoma): nonfamilial or familial, e.g., MEN 1, MEN 2, HPT-JT, FIHP
Tertiary hyperparathyroidism (hyperplasia or adenoma in chronic renal failure)
LOW PARATHYROID HORMONE LEVELS
Malignancy*
Primary
• Parathyroid hormone–related peptide (PTHrP): carcinoma of lung, esophagus, renal cell, ovary, and bladder
• Excess production of $1,25(OH)_2D$ (lymphoma)
Secondary
• Lytic bone metastases* (multiple myeloma* and breast carcinoma*)
• Other location, ectopic factors (e.g., cytokines)
Excess vitamin D
Exogenous vitamin D toxicity by parent D compound, 25(OH) vitamin D_3, or $1,25(OH)_2$ vitamin D_3 in vitamin preparations, cod liver oil, herbal medicines
Endogenous production of 25(OH) vitamin D_3—Williams syndrome
Endogenous production of $1,25(OH)_2$ vitamin D_3, for example, granulomatous disorders (sarcoidosis, HIV, TB, histoplasmosis, coccidioidomycosis, leprosy), lymphoma, and infantile hypercalcemia
Drugs
Thiazide diuretics
Lithium
Total parenteral nutrition
Estrogens/antiestrogens, testosterone
Milk-alkali syndrome
Vitamin A toxicity
Aluminum intoxication (in chronic renal failure)
Aminophylline
Nonparathyroid endocrine disorders
Thyrotoxicosis
Pheochromocytoma
Acute adrenal insufficiency
Vasoactive intestinal polypeptide hormone–producing tumor (VIPoma)
Immobilization
INAPPROPRIATE PARATHYROID HORMONE LEVELS DUE TO ALTERED SET POINT
Familial benign hypocalciuric hypercalcemia (FBH or FHH) types 1-3

*Most common causes.

hyperparathyroidism with jaw tumors. Syndromic and nonsyndromic forms of primary hyperparathyroidism may also occur as hereditary (i.e., familial) disorders, or as nonfamilial (i.e., sporadic) diseases.

Primary Hyperparathyroidism

EPIDEMIOLOGY

Primary hyperparathyroidism, which affects 3 in 1000 adults, is one of the two most common causes of hypercalcemia and is due to an excessive secretion of PTH from a parathyroid adenoma, parathyroid hyperplasia, or rarely, a parathyroid carcinoma.[8] Studies have estimated that the global prevalence of parathyroid tumors is 4 million. Primary hyperparathyroidism usually occurs as a nonsyndromic isolated endocrinopathy between the ages of 40 and 65 years, and it is three times more common in females than males.

PATHOBIOLOGY

Eighty percent of patients with primary hyperparathyroidism will have a solitary parathyroid adenoma, and 15 to 20% of patients will have hyperplasia involving all four parathyroid glands. Parathyroid carcinoma occurs in less than 0.5% of patients with primary hyperparathyroidism. The underlying causes of primary hyperparathyroidism are largely unknown. However, more than 10% of patients with clinically nonfamilial primary hyperparathyroidism occurring before 45 years of age have a germline mutation in 1 of 12 genes, including those of MEN 1 (*MEN1*), cell division cycle 73 (*CDC73*), and calcium-sensing receptor (*CaSR*). In addition, studies of nonfamilial sporadic parathyroid adenomas have shown that 35 to 50% have somatic mutation of the *MEN1* gene; 15% have overexpression of cyclin D1; and more than 85% have an abnormality of the Wnt/β-catenin pathway.

CLINICAL MANIFESTATIONS

Most patients with primary hyperparathyroidism have mild, asymptomatic hypercalcemia, detected by chance at the time of biochemical screening for other reasons. However, nearly 50% of these patients may have subtle neuromuscular symptoms, such as fatigue and weakness, that become apparent only in retrospect after a successful parathyroidectomy.

Symptomatic hypercalcemia (see Table 227-2) predominantly affects the skeletal,[9] renal, and gastrointestinal systems. Because of early diagnosis, the classic skeletal changes of osteitis fibrosa cystica due to subperiosteal resorption of the distal phalanges, tapering of the distal clavicles, a salt-and-pepper appearance of the skull, bone cysts, and brown tumors of the long bones are now identified in less than 5% of patients. However, osteopenia, as assessed by bone mineral density, occurs in 25% of patients, primarily of the cortical bone (e.g., distal third of forearm) rather than the cancellous bone (e.g., lumbar spine). The hip bones, which are an equal mixture of cortical and cancellous bone, show intermediate reductions in bone mineral density. Overall, however, the risk for bone fractures in patients with mild primary hyperparathyroidism is similar to those in matched, normal controls. Renal stone disease (nephrolithiasis [Chapter 111] and nephrocalcinosis) occurs in 20% of patients, hypercalciuria occurs in 30% of patients, and renal impairment also can occur. The gastrointestinal manifestations include peptic ulcers (Chapter 125) and pancreatitis (Chapter 130).

DIAGNOSIS

In the presence of hypercalcemia, the finding of an elevated circulating PTH concentration by an immunoradiometric or immunochemiluminometric assay establishes the diagnosis. PTH is elevated in approximately 90% of patients with primary hyperparathyroidism, who invariably have hypercalcemia (see Fig. 227-2).[10] The only other hypercalcemic disorders in which PTH may occasionally be elevated are familial benign hypocalciuric hypercalcemia, immobilization, or the use of lithium or thiazide (see Table 227-3). A careful history and cessation of drug use help to exclude these possibilities.

About one-third of patients with primary hyperparathyroidism have a low serum phosphate level (see Fig. 227-2), which otherwise is in the lower range of normal. In addition, some patients have a mild increase in the serum chloride concentration and a concomitant decrease in the bicarbonate concentration. Serum alkaline phosphatase activity may be elevated in some patients, and urinary calcium excretion is increased in 30% of patients. The circulating $1,25(OH)_2D$ concentration is elevated in some patients with primary hyperparathyroidism, although it is not of diagnostic value because it is also elevated in other hypercalcemic disorders such as sarcoidosis and lymphomas (see Fig. 227-2). The serum 25-OH-D concentration is within the normal range. Densitometric scanning can detect early skeletal changes and is useful for deciding on whether conservative as opposed to surgical management is most appropriate (Table 227-5).

Preoperative localization to define the sites of the parathyroid tumors includes ultrasonography,[11] computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy with technetium-99m sestamibi. Sestamibi scintigraphy with CT (e.g., single-photon emission computed tomography [SPECT]) is the preferred test to give a three-dimensional image with anatomic resolution,[12] but the appreciable incidence of false-positive tests with each of the noninvasive localization procedures means that a confirmation using two methods is preferable. Invasive localization tests (arteriography and selective venous sampling for PTH in the veins draining the thyroidal

TABLE 227-5 SUMMARY OF GUIDELINES FOR PARATHYROID SURGERY IN PRIMARY HYPERPARATHYROIDISM PATIENTS

Surgery* recommended if patient meets any one of the following criteria:

- Any complication of primary hyperparathyroidism (e.g., nephrolithiasis, nephrocalcinosis or bone erosions of osteitis fibrosa cystica)
- An episode of life-threatening hypercalcemia
- Serum calcium >1 mg/dL (0.25 mmol/L) above upper limit of normal
- Marked hypercalciuria (>400 mg/24 hr [>10 mmol/24 hr] in men and >300 mg/24 hr [>7.5 mmol/24 hr] in women) and an increased risk for nephrolithiasis by biochemical stone risk analysis
- Significant reduction in creatinine clearance (i.e., <60 mL/min)
- Reduction in bone mineral density (i.e., T score below –2.5, at lumbar spine, total hip, femoral neck or distal 1/3 of radius and/or previous vertebral fracture)
- Age <50 years

*Surgery is also indicated in patients for whom medical surveillance is neither desired nor possible.
Adapted from Bilezikian JP, Silverberg SJ, Bandeira F, et al. Management of primary hyperparathyroidism. *J Bone Miner Res.* 2022;37:2391-2403.

region) are time consuming, expensive, difficult, and dependent on the skill of the radiologist, so they generally should be reserved for patients who have had previous unsuccessful neck surgery.

TREATMENT

The natural history of primary hyperparathyroidism in most patients is to progress slowly or not at all. For example, among asymptomatic patients, only 25% have progressive disease, which is usually manifested as a decrease in bone mineral density during a 10-year period. For patients with asymptomatic primary hyperparathyroidism, active surveillance is as good as parathyroidectomy,[A1] and even mildly symptomatic patients who do not undergo surgery appear to do as well with medical management for a decade.[A2]

Parathyroidectomy

Parathyroidectomy is recommended for more than minimally symptomatic patients and for patients who have skeletal and renal complications (see Table 227-5). Parathyroidectomy is a safe procedure, generally performed under local anesthesia, that achieves a biochemical cure in about 98% of patients,[13] if undertaken by an experienced surgeon. Successful parathyroidectomy leads to an increase in bone mineral density over a 6- to 12-month period; this improvement continues for up to 10 years and in older adults is associated with a lower risk of fractures.[14] Complications of parathyroid surgery include damage to the recurrent laryngeal nerve and permanent hypoparathyroidism. Thermal ablation, which is an option in patients who are not good candidates for anesthesia and open surgery, is reported to have a cure rate of about 90%.[15]

Watchful Waiting

Patients who do not undergo parathyroidectomy (e.g., patients with asymptomatic primary hyperparathyroidism) should be monitored with annual measurement of the serum calcium level, PTH level, and 25-OH-D level; formal measurement of creatinine clearance (rather than an estimated glomerular filtration rate [eGFR]); 24-hour urinary calcium excretion; and bone mineral density. Patients should also have a radiograph of the spine if they have lost height or have back pain. If nephrolithiasis is suspected, abdominal imaging (e.g., ultrasonography, radiography, or computed tomographic scanning) should be obtained. In addition, patients with primary hyperparathyroidism also should avoid dehydration and remain ambulant. Any vitamin D deficiency should be corrected cautiously with oral vitamin D supplementation aimed at maintaining the serum 25-OH-D above 50 nmol/L. The dietary intake of calcium should be normal. Thiazide diuretics and herbal and tonic remedies that may contain vitamin D or vitamin A should be avoided.

Medical Therapy

The goals of medical therapy are to minimize the loss of bone mineral density and secondarily to normalize levels of serum calcium and PTH. Medications should be chosen based on the aims of the treatment. For example, bisphosphonate therapy should be chosen if the aim is to increase bone mineral density, and cinacalcet should be chosen if the aim is to reduce serum calcium concentrations. Combined use of cinacalcet and alendronate can normalize hypercalcemia and improve bone mineral density in patients with primary hyperparathyroidism.

Cinacalcet (initially 30 mg twice daily; maximum 90 mg 4 times a day, adjusted every 2 to 4 weeks according to response) can lower serum calcium concentrations to normal values with long-term treatment, with modest reductions in PTH levels and no major adverse effects in patients with primary hyperparathyroidism. However, bone mineral density in the treated patients remains unchanged despite a reduction in biochemical markers for bone resorption and formation. The use of cinacalcet is approved for adults (i.e., over age of 18 years) who have severe hypercalcemia due to primary hyperparathyroidism and are unable to undergo parathyroidectomy, have hypercalcemia due to inoperable parathyroid carcinoma, or are on dialysis with uncontrolled secondary hyperparathyroidism.

The bisphosphonates (e.g., alendronate 10 mg orally daily; see Table 225-2) inhibit bone resorption and improve bone mineral density at the lumbar spine but do not alter serum calcium or PTH concentrations. Daily high-dose (70 mg or 2800 U) cholecalciferol also can decrease PTH and improve bone density when used for 6 months before and after parathyroidectomy. However, these effects are not sustained. Denosumab (a RANKL inhibitor given as 60 mg once every 6 months by subcutaneous injections) is an alternative to improve bone mineral density in osteoporotic patients with primary hyperparathyroidism. Estrogens increase bone density in postmenopausal women with primary hyperparathyroidism, but they have only small effects on the concentrations of serum calcium and PTH and are recommended only when other drugs are contraindicated, not available, or unaffordable.

Familial Primary Hyperparathyroidism

Primary hyperparathyroidism is most frequently encountered as a nonfamilial (sporadic) disorder. However, approximately 10% of patients with primary hyperparathyroidism have a hereditary form that may either be part of the multiple endocrine neoplasia (MEN; Chapter 212) 1, MEN 2, MEN 3, and MEN 4 syndromes or part of the hyperparathyroidism-jaw tumor syndrome. In addition, hereditary primary hyperparathyroidism may develop as a solitary endocrinopathy, termed familial isolated hyperparathyroidism. Patients with these familial forms of primary hyperparathyroidism, including the MEN syndromes, have an earlier age of onset (20 to 25 years vs. 55 years) and an equal male : female ratio (1 : 1 vs. 1 : 3). Familial isolated hyperparathyroidism has been reported in several kindreds, some of which harbor mutations of the *MEN1*, *CDC73*, *GCM2* or *CaSR* genes (see Table 227-1 and E-Fig. 227-1). The familial syndromes associated with MEN 1, MEN 2, MEN 3, and MEN 4 are reviewed in detail in Chapter 212.

The hyperparathyroidism-jaw tumor syndrome is an autosomal dominant disorder characterized by the occurrence of parathyroid tumors, which may be carcinomas in approximately 15% of patients, and ossifying fibromas that usually affect the maxilla or mandible. In addition, some patients may also develop Wilms tumors, renal cysts, renal hamartomas, renal cortical adenomas, papillary renal cell carcinomas, uterine tumors that may be malignant, pancreatic adenocarcinomas, testicular mixed germ cell tumors with a major seminoma component, and Hurthle cell thyroid adenomas. Mutations of the *CDC73* gene, which is located on chromosome 1q31.2 and encodes a 531–amino acid protein, parafibromin, cause the syndrome.

MEN syndromes are associated with multiple parathyroid tumors, rather than the solitary parathyroid adenomas typically found in the sporadic form, and hyperparathyroidism-jaw tumor syndrome is associated with parathyroid carcinoma in 15% of patients. Minimally invasive parathyroidectomy is an unsuitable approach in MEN patients because of multigland disease, and patients with hyperparathyroidism-jaw tumor syndrome are likely to require early surgery because of their higher risk for parathyroid carcinoma.

Uremic Hyperparathyroidism

PATHOBIOLOGY

Serum PTH levels rise in response to hypocalcemia, regardless of the cause, but this secondary hyperparathyroidism usually resolves with treatment of the underlying cause (Table 227-6). In chronic renal failure (Chapter 116), however, the secondary hyperparathyroidism may persist for a longer time,[16] and eventually the parathyroid cells can become autonomous and secrete excessive PTH despite normocalcemic and even hypercalcemia. This state, termed tertiary hyperparathyroidism (see Table 227-2),[17] results when early, presumably polyclonal, secondary hyperplasia evolves into monoclonal tumors. Elevations in blood phosphate levels associated with chronic renal failure (Chapter 116) independently of calcitriol and calcium lead to increased production of PTH and nodular hyperplasia of the parathyroid glands, thereby promoting the parathyroid gland's resistance to calcitriol and calcium. The processes leading to tertiary hyperparathyroidism are not fully understood but appear to involve genes other than those involved in the sporadic and familial forms of primary hyperparathyroidism.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In chronic renal failure (Chapter 116), phosphate retention and decreased production of $1,25(OH)_2D$ result in hypocalcemia and secondary hyperparathyroidism. This combination of biochemical abnormalities results in renal osteodystrophy, which is a severe bone disease that shows combined features

TABLE 227-6 CAUSES OF HYPOCALCEMIA

LOW PARATHYROID HORMONE LEVELS (HYPOPARATHYROIDISM)
Parathyroid agenesis
Isolated or part of complex developmental anomaly (e.g., DiGeorge syndrome)
Parathyroid destruction
Surgery*
Radiation
Infiltration by metastases or systemic disease (e.g., hemochromatosis, amyloidosis, sarcoidosis, Wilson disease, thalassemia)
Autoimmune
Isolated
Polyglandular (type 1)
Reduced parathyroid function (i.e., parathyroid hormone secretion)
Parathyroid hormone gene defects
Hypomagnesemia*
Neonatal hypocalcemia (may be associated with maternal hypercalcemia)
Hungry bone disease (postparathyroidectomy)
Calcium-sensing receptor or Gα11 mutations
HIGH PARATHYROID HORMONE LEVELS (SECONDARY HYPERPARATHYROIDISM)
Vitamin D deficiency*
As a result of nutritional lack,* malabsorption,* liver disease, or vitamin D receptor defects
Inadequate production of active vitamin D ($1,25[OH]_2D$) as a result of chronic renal failure*
Vitamin D resistance (rickets)
As a result of renal tubular dysfunction (Fanconi syndrome) or vitamin D receptor defects
Parathyroid hormone resistance
(e.g., pseudohypoparathyroidism, hypomagnesemia)
Drugs
Calcium chelators (e.g., citrated blood transfusions, phosphate—cow's milk is rich in phosphate)
Inhibitors of bone resorption (e.g., bisphosphonates, calcitonin, plicamycin)
Altered vitamin D metabolism (e.g., phenytoin, ketoconazole)
Foscarnet
Miscellaneous
Acute pancreatitis
Acute rhabdomyolysis
Massive tumor lysis
Osteoblastic metastases (e.g., from prostate or breast carcinoma)
Toxic shock syndrome
Hyperventilation

*Most common causes.

of hyperparathyroidism and vitamin D deficiency, including bone erosions and osteomalacia. The diagnosis is established by the presence of an elevated level of PTH despite normocalcemia or hypercalcemia.

TREATMENT

Treatment is based on correcting the hypocalcemia and hyperphosphatemia (Chapter 116). Calcitriol (0.5 to 1.0 μg daily) increases the intestinal absorption of both calcium and phosphate and can suppress the development of hyperparathyroidism. However, calcitriol should not be given if the serum phosphorus level is greater than 5.5 mg/dL because increased vitamin D–mediated intestinal phosphate absorption will worsen hyperphosphatemia and increase the risk of soft tissue calcification. Careful monitoring is needed to avoid hypercalcemia or urinary calcium values above 250 mg/day, a level that increases the risk of developing kidney stones.

If dietary restriction cannot maintain serum phosphorus at or below 5.5 mg/dL, sevelamer (400- to 800-mg tablets, initially 1.2 g/day in divided doses) is generally preferred because it reduces hyperphosphatemia and is associated with a lower all-cause mortality than other options.[A3] When the serum phosphorus level is over 7 mg/dL, aluminum-based binders (600 mg of concentrated aluminum hydroxide solution with each meal) are effective but should be used for no more than 1 week to avoid aluminum neurotoxicity.

Early treatment of the metabolic disturbance will prevent or delay the onset of severe secondary hyperparathyroidism and tertiary hyperparathyroidism, which requires parathyroidectomy.[18] For patients who have end-stage renal failure and are on dialysis, cinacalcet (initially 30 mg once daily, adjusted every 2 to 4 weeks according to response to a maximum of 180 mg per day), which is the allosteric activator of the calcium sensing receptor, can be used to treat the severe secondary hyperparathyroidism. Cinacalcet will reduce the PTH concentrations and may also have an antiproliferative effect, but subtotal parathyroidectomy is better than cinacalcet for controlling hypercalcemia in kidney allograft recipients (Chapter 117).[A4]

ENDOCRINE CAUSES OF HYPERCALCEMIA OTHER THAN HYPERPARATHYROIDISM

Nonparathyroid disorders (see Table 227-3) that are associated with hypercalcemia include thyrotoxicosis (Chapter 207), pheochromocytoma (Chapter 209), Addison disease (Chapter 208), vasoactive intestinal polypeptide hormone producing tumor (VIPomas; Chapter 126), familial benign hypocalciuric hypercalcemia, Jansen disease, and Williams syndrome.

Thyrotoxicosis

The mild hypercalcemia (<12 mg/dL, or 3 mmol/L) that frequently accompanies thyrotoxicosis (Chapter 207) leads to increased bone turnover and resorption. The hypercalcemia, which may respond rapidly to treatment with β-adrenergic blockers, as well as more gradually to lowering the serum thyroxine over weeks to months, usually resolves when the hyperthyroidism resolves.

Familial Benign Hypocalciuric Hypercalcemia

Familial benign hypercalcemia, which is also referred to as familial hypocalciuric hypercalcemia, is an autosomal dominant disorder characterized by lifelong asymptomatic hypercalcemia in association with an inappropriately low urinary calcium excretion (i.e., calcium clearance-to-creatinine clearance ratio [CCR] <0.01) and normal circulating PTH concentrations in 80% of patients. Hypermagnesemia is also typically present. Although most patients with familial hypocalciuric hypercalcemia are asymptomatic, chondrocalcinosis and acute pancreatitis have occasionally been observed. Familial hypocalciuric hypercalcemia is a genetically heterogenous disorder with three subtypes (FHH1, FHH2, and FHH3 due to mutations in the calcium sensing receptor, the G-protein alpha 11 subunit, and the adaptor protein 2 sigma subunit, respectively). Patients with familial hypocalciuric hypercalcemia have been misdiagnosed as having primary hyperparathyroidism because 20% of these patients may have elevated plasma PTH concentrations. In addition, 20% of patients with familial hypocalciuric hypercalcemia may have a creatinine clearance ratio greater than 0.01 and therefore be indistinguishable from patients with primary hyperparathyroidism. Genetic analysis, which is required to distinguish patients with familial hypocalciuric hypercalcemia from patients with primary hyperparathyroidism, is important because the hypercalcemia in familial hypocalciuric hypercalcemia is generally benign and does not result in sequelae (see Table 227-2). Moreover, parathyroidectomy does not correct the hypercalcemia in familial hypocalciuric hypercalcemia. If it is symptomatic or severe, cinacalcet (30 to 60 mg daily) may be used to correct the hypercalcemia and improve symptoms.

Autoimmune Hypocalciuric Hypercalcemia

Some patients who have the clinical features of familial hypocalciuric hypercalcemia but none of the three causative mutations may have autoimmune hypocalciuric hypercalcemia. These patients have circulating antibodies to the extracellular domain of the CaSR, and the CaSR-bound autoantibodies stimulate PTH release from human parathyroid cells. Thus, autoimmune hypocalciuric hypercalcemia is a disorder of extracellular calcium sensing that should be considered in patients who have familial hypocalciuric hypercalcemia without known mutations. Manifestations include hyperthyroidism, hypothyroidism, or celiac disease, but patients can be asymptomatic if they have not yet developed any clinical features. These patients may have multiple autoimmune levels of antithyroid, antigliadin, or antiendomysial antibodies. The effects of treatment with glucocorticoids (usually prednisolone initially as high as 5 to 60 mg/day) have been variable.

Williams Syndrome

Williams syndrome is an autosomal dominant disorder characterized by supravalvular aortic stenosis, elfin-like facies, psychomotor retardation, and infantile hypercalcemia. The underlying abnormality causing hypercalcemia, which affects 5 to 50% of patients, remains unknown, but abnormal $1,25(OH)_2D_3$ metabolism and decreased calcitonin production have been implicated. Hemizygosity for a microdeletion of chromosome 7q11.23, which involes the *ELASTIN* and *LIM-KINASE* genes, may explain the respective cardiovascular and neurologic features. Treatment is as for hypercalcemia.

Malignancy

Hypercalcemia may occur in 20 to 30% of patients with a malignancy, usually due to increased bone resorption, which may be either directly due to skeletal metastases or indirectly due to tumor production of a humoral factor that stimulates osteoclastic bone resorption (Chapter 164).[19] The cancers that

typically metastasize to produce lytic bone lesions are breast cancer (Chapter 183), lymphomas (Chapters 171 and 172), or multiple myeloma (Chapter 173; see Table 227-3).[20] The associated osteolysis, mediated by recruitment and activation of osteoclasts, involves cytokines. The cancers that are typically associated with the humoral hypercalcemia of malignancy are squamous carcinomas of the lung (Chapter 177), esophagus (Chapter 178), cervix (Chapter 184), vulva (Chapter 184), skin (Chapter 188), head, or neck (Chapter 176), but other types from the kidney (Chapter 182), bladder, ovary, and breast (Chapter 183) may also occur.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Humoral hypercalcemia of malignancy accounts for up to 80% of patients with malignancy-associated hypercalcemia. The most common factor causing humoral hypercalcemia of malignancy is PTHrP, which can be measured in the serum by immunoassay. However, these assays are relatively insensitive, and the failure to detect serum PTHrP does not exclude the diagnosis. Patients with humoral hypercalcemia of malignancy generally have hypercalcemia associated with lower or undetectable serum PTH levels, marked hypercalcemia, and a reduced plasma $1,25(OH)_2D$ level. When bone metastases are the direct cause of hypercalcemia, the serum phosphate level is typically elevated.

TREATMENT

Therapy of humoral hypercalcemia of malignancy is aimed at (1) reducing the tumor load by surgery, radiotherapy, or chemotherapy; (2) reducing osteoclastic bone resorption by use of denosumab[A5] (120 mg subcutaneously on weeks 1, 2, and 3 and then every 4 weeks) plus zoledronate[A6] (4 mg typical dose, adjusted by expert consultation based on renal function, given intravenously over 15 to 30 minutes; may repeat the dose once 7 or more days later) or calcitonin (4 to 8 units/kg intramuscularly or subcutaneously every 12 hours for 2 to 3 days); and (3) increasing renal calcium clearance by a saline diuresis.[21]

For patients with bone metastases, treatment of the underlying tumor is critical.[22] Saline diuresis (see Treatment of Symptomatic Hypercalcemia) can be helpful.

Granulomatous Disorders

The granulomatous disorders that are associated with hypercalcemia (see Table 227-3) are invariably associated with elevated circulating concentrations of $1,25(OH)_2D$ owing to extrarenal synthesis. Sarcoidosis (Chapter 83) is the most frequently encountered granulomatous disorder associated with hypercalcemia; 10% of patients with sarcoidosis have hypercalcemia, and about half become hypercalciuric. The finding of raised serum angiotensin-converting enzyme (ACE) activity may help confirm the diagnosis.

TREATMENT

Glucocorticoids (e.g., 40 to 60 mg of prednisolone daily) decrease $1,25(OH)_2D$ production and restore the calcium concentration to normal by reducing intestinal absorption of calcium. Once normocalcemia is achieved, chronic dosing is highly variable depending on what may be required to maintain normocalcemia. Failure to achieve normal serum calcium concentrations within 10 days of glucocorticoid therapy suggests the coexistence of another cause for the hypercalcemia, such as primary hyperparathyroidism or malignancy.

Drugs

Several drugs (see Table 227-3) can cause hypercalcemia by different mechanisms. Compounds containing vitamins D and A are common and frequently associated with hypercalcemia. Thiazide diuretics are often associated with hypercalcemia owing to enhanced reabsorption of calcium in the distal renal tubule; hypercalcemia reverses rapidly with discontinuation of the drug.

The consumption of large quantities of milk or calcium carbonate for symptoms of acid-peptic disease (Chapter 125) may contribute to moderate to severe hypercalcemia with alkalosis and renal impairment. The amount of calcium ingested by patients with this syndrome is usually 5 to 15 g/day. Treatment consists of discontinuing the ingestion of the calcium-containing compounds and antacids, rehydration, and saline diuresis.

HYPOCALCEMIA

DEFINITION

Hypocalcemia is defined as a serum calcium concentration below the lower limit of normal range: an ionized serum calcium below 4.65 mg/dL (1.16 mmol/L) and a total serum calcium below 8.5 mg/dL (2.12 mmol/L). Mild hypocalcemia is defined as a total serum calcium of 8 to 8.5 mg/dL (2 to 2.12 mmol/L) and severe hypocalcemia as a total serum calcium below 7.6 mg/dL (1.9 mmol/L).

PATHOBIOLOGY

Hypocalcemia (see Table 227-6) can be classified by cause, according to whether serum PTH concentrations are low (i.e., hypoparathyroid disorders) or high (i.e., disorders associated with secondary hyperparathyroidism). Hypocalcemia is most commonly caused by hypoparathyroidism, a deficiency or abnormal metabolism of vitamin D, acute or chronic renal failure, or hypomagnesemia. Hypocalcemic diseases may arise because of a failure of the parathyroid glands to develop, destruction of the parathyroid glands, reduced PTH secretion, or reduced PTH-mediated actions in target tissues owing to a defect in the PTH receptor (i.e., the PTH/PTHrP receptor), or insensitivity to PTH caused by defects downstream of the PTH/PTHrP receptor (see E-Fig. 227-1).[23] The diseases also may be classified as being part of the hypoparathyroid disorders, of the CaSR abnormalities, or of the pseudohypoparathyroid disorders.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of hypocalcemia ranges from an asymptomatic biochemical abnormality to a severe, life-threatening condition. In mild hypocalcemia, patients may be asymptomatic. Patients with more severe and long-term hypocalcemia may develop acute symptoms of neuromuscular irritability (Table 227-7), ectopic calcification (e.g., in the basal ganglia, which may be associated with extrapyramidal neurologic symptoms), subcapsular cataracts, papilledema, and abnormal dentition. Investigations should be directed at confirming the presence of hypocalcemia and establishing the cause (Fig. 227-3).

In hypoparathyroidism, serum calcium is low, phosphate is high, and PTH is undetectable; renal function and concentrations of the 25-hydroxy and 1,25-dihydroxy metabolites of vitamin D are usually normal (see Fig. 227-3). The features of pseudohypoparathyroidism are similar to those of hypoparathyroidism except for PTH, which is markedly increased. In chronic renal failure (Chapter 116), which is the most common cause of hypocalcemia, phosphate is high; alkaline phosphatase, creatinine, and PTH are elevated; 25-OH-D_3 is normal; and $1,25(OH)_2D_3$ is low (see Fig. 227-1). In vitamin D deficiency osteomalacia (Chapter 226), serum calcium and phosphate are low, alkaline phosphatase and PTH are elevated, renal function is normal, and 25-OH-D_3 is low (see Fig. 227-3).[24] The most frequent artifactual cause of hypocalcemia is hypoalbuminemia, such as occurs in severe cirrhosis (Chapter 139) or the nephrotic syndrome (Chapter 107).

TABLE 227-7 HYPOCALCEMIC CLINICAL FEATURES OF NEUROMUSCULAR IRRITABILITY

Paresthesia, usually of fingers, toes, and circumoral regions
Tetany, carpopedal spasm, muscle cramps
Chvostek sign*
Trousseau sign†
Seizures of all types (i.e., focal or petit mal, grand mal, or syncope)
Prolonged QT interval on electrocardiogram
Laryngospasm
Bronchospasm

*Chvostek sign is twitching of the circumoral muscles in response to gentle tapping of the facial nerve just anterior to the ear; it may be present in 10% of normal individuals.

†Trousseau sign is carpal spasm elicited by inflation of a blood pressure cuff to 20 mm Hg above the patient's systolic blood pressure for 3 minutes.

TREATMENT

Acute Hypocalcemia

The management of acute hypocalcemia depends on the severity of the hypocalcemia, the rapidity with which it developed, and the degree of neuromuscular irritability (see Table 227-7). Treatment should be given to symptomatic patients (e.g., with seizures or tetany) and asymptomatic patients with a serum calcium of less than 7.6 mg/dL (1.90 mmol/L) who are at high risk for developing complications.

The preferred treatment for acute symptomatic hypocalcemia is calcium gluconate, 10 mL 10% w/v (2.20 mmol of calcium) intravenous, diluted in 50 mL of 5% dextrose or 0.9% sodium chloride and given by slow injection (>5 minutes); this injection can be repeated as required to control symptoms. Serum calcium concentrations should be assessed regularly. Persistent hypocalcemia may be managed acutely by administration of a calcium gluconate infusion; for example, dilute 10 ampules of calcium gluconate, 10 mL 10% w/v (22 mmol of

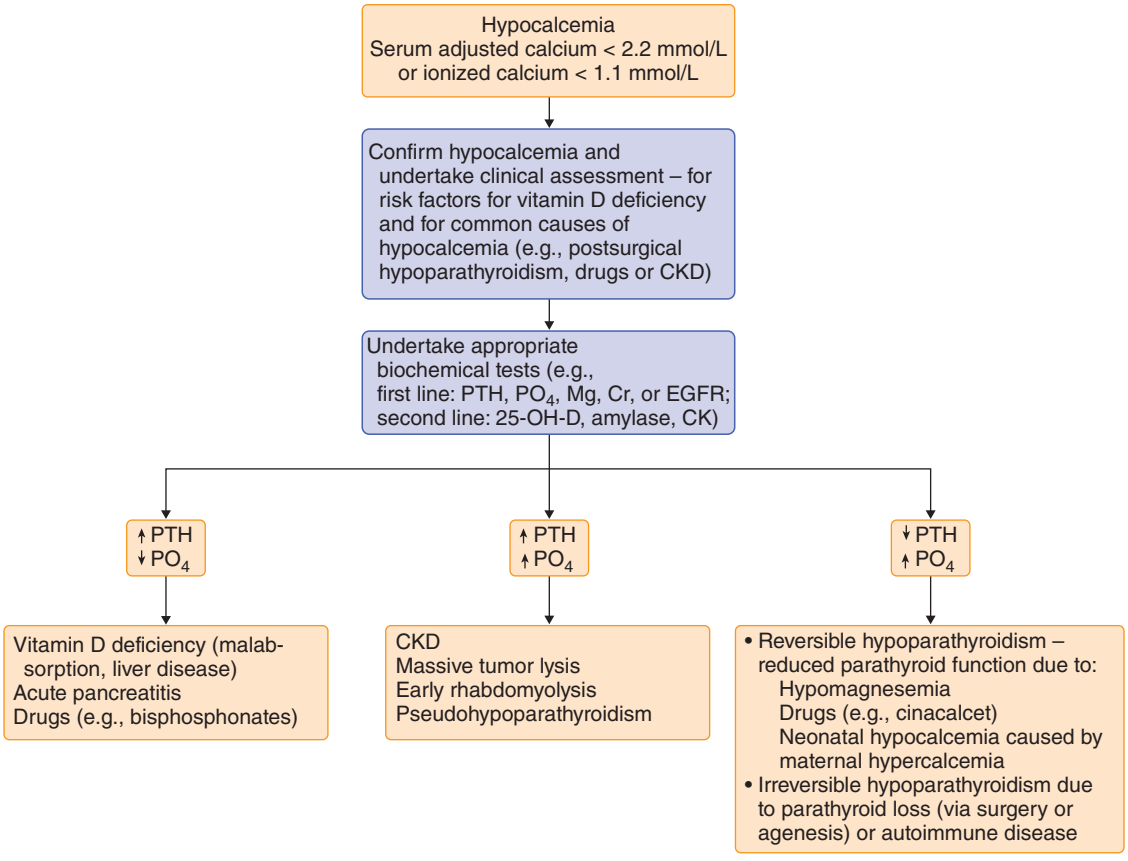

FIGURE 227-3. Clinical approach to investigation of causes of hypocalcemia. 25-OH-D = 25-hydroxyvitamin D; CK = creatinine kinase; CKD = chronic kidney disease; Cr = creatinine; EGFR = estimated glomerular filtration rate; Mg = magnesium; PO_4 = phosphate; PTH = parathyroid hormone.

calcium), in 1 L of 5% dextrose or 0.9% sodium chloride, start infusion at 50 mL/hour, and titrate to maintain serum calcium concentrations in the normal range. Generally, 1.2 to 1.6 mg/kg (0.3 to 0.4 mmol/kg) of elemental calcium infused over 4 to 6 hours increases serum calcium by 2 to 3 mg/dL (0.5 to 0.75 mmol/L).

If hypocalcemia is likely to persist, oral vitamin D therapy (see later) should also be administered. In hypocalcemic patients who are also hypomagnesemic (which may be found in the postparathyroidectomy period or in patients who have severe malabsorption, such as, for example, with celiac disease [Chapter 126]), the hypomagnesemia must be corrected before the hypocalcemia will resolve.

Chronic Hypocalcemia

The three main agents available for the treatment of chronic (long-term) hypocalcemia are vitamin D, supplemental calcium (about 10 to 20 mmol calcium every 6 to 12 hours), and PTH. Close monitoring (at about 1- to 2-week intervals) of the patient's serum and urine calcium concentrations is required initially, and follow-up at 3- to 6-month intervals is appropriate once stabilization is achieved. The aim is to avoid hypercalcemia, hypercalciuria (which may occur in the absence of hypercalcemia), nephrolithiasis, and renal failure.

For treatment of hypocalcemia due to hypoparathyroidism or chronic renal failure, calcitriol (0.25 to 2 mg/day) is the drug of choice because it is the active metabolite and, unlike alfacalcidol, does not require hepatic 25-hydroxylation. Other vitamin D preparations include vitamin D_3 (cholecalciferol), vitamin D_2 (ergocalciferol), 10,000 to 50,000 units (0.25 to 1.25 mg/day); or alfacalcidol (1α-hydroxycholecalciferol), 0.25 to 1 μg/day. Cholecalciferol and ergocalciferol are the least expensive preparations but have the longest durations of action and may result in prolonged toxicity; however, they are the preparations of choice for treating hypocalcemia associated with vitamin D deficiency (see Table 227-6). The other preparations, which do not require renal 1α-hydroxylation, have the advantage of shorter half-lives and thereby minimize the risk for prolonged toxicity.

Patients with hypoparathyroidism seldom require calcium supplements after the early stages of stabilization with vitamin D. In hypoparathyroid patients, PTH can improve the biochemical and skeletal indices, as well as mental and physical health.

CAUSES OF HYPOCALCEMIA

HYPOPARATHYROIDISM

Hypoparathyroidism is characterized by hypocalcemia and hyperphosphatemia, which are the result of a deficiency in PTH secretion or action.[25]

The incidence of hypoparathyroidism is approximately 0.8 per 100,000 person-years, with a prevalence estimated to be 22 to 37 per 100,000 person-years.

The most common cause of hypoparathyroidism is postsurgical hypoparathyroidism. Hypoparathyroidism also may result from agenesis (e.g., DiGeorge syndrome) or destruction of the parathyroid glands (e.g., autoimmune diseases), from reduced secretion of PTH (e.g., neonatal hypocalcemia or hypomagnesemia), or from resistance to PTH (which may occur as a primary disorder (e.g., pseudohypoparathyroidism or secondary to hypomagnesemia) (see Table 227-6). In addition, hypoparathyroidism may occur as an inherited syndromic disorder (see Table 227-1) that may either be part of a complex congenital defect or part of a polyglandular autoimmune disorder (Chapter 212; see Table 227-6 and E-Fig. 227-1). Hypoparathyroidism may also occur as a nonsyndromic solitary endocrinopathy, which has been referred to as isolated or idiopathic hypoparathyroidism. Familial isolated hypoparathyroidism with autosomal dominant, autosomal recessive, and X-linked recessive inheritances also occur.

Isolated Hypoparathyroidism

Isolated hypoparathyroidism may either be inherited or acquired by damage to the parathyroids at surgery, by infiltrating metastases, or by systemic disease (see Table 227-6).

Acquired Forms of Hypoparathyroidism

Hypoparathyroidism may occur after neck surgery,[26] after irradiation, or because of infiltration by metastases or systemic disease, for example, hemochromatosis (Chapter 196), amyloidosis (Chapter 174), sarcoidosis (Chapter 83), Wilson disease (Chapter 195), or thalassemia (Chapter 148) (see Table 227-6). Surgical damage to the parathyroids occurs most commonly after a radical neck dissection, such as for laryngeal or esophageal carcinoma treatment, after a total thyroid resection, or after repeated parathyroidectomies for polyglandular disease (e.g., in MEN 1 or MEN 2, discussed previously). Hypocalcemic symptoms begin 12 to 24 hours after surgery and may require treatment with oral or intravenous calcium.

Functional hypoparathyroidism, which may result from severe hypomagnesemia (<0.4 mmol/L), may be due to a severe intestinal malabsorption disorder (e.g., Crohn disease; Chapters 126 and 127) or a renal tubular disorder (Chapters 104 and 108; see Table 227-6). It is

associated with hypoparathyroidism because magnesium is required for the release of PTH from the parathyroid gland and also for PTH action through adenyl cyclase

Inherited Hypoparathyroidism

Patients with inherited autosomal dominant, autosomal recessive, and X-linked hypoparathyroidism (see Table 227-1) may develop hypocalcemic seizures in the neonatal or infantile periods. Some of the autosomal forms are due to mutations of the *PTH* gene, *CaSR*, the *Gα11* subunit (see later), and the transcriptional factor *GCMB* (glial cells missing B). The X-linked forms likely alter regulation of SOX3 (see Fig. 227-3).

AUTOSOMAL DOMINANT HYPOCALCEMIA TYPE 1 AND TYPE 2. Autosomal dominant hypocalcemia type 1 is due to gain-of-function mutations of the *CaSR* (see Table 227-1 and E-Fig. 227-1), although about 20% of patients may not have a previously reported family history because they have de novo mutations. Autosomal dominant hypocalcemia type 1 is characterized by lifelong mild or severe hypocalcemia in association with normal serum PTH concentrations in about 40% of patients or low serum PTH concentrations in about 60% of patients. Serum phosphate and magnesium concentrations may be elevated or low, respectively. Approximately 50% of these patients have asymptomatic hypocalcemia, and the remaining 50% may experience paresthesia, muscle cramps, carpopedal spasms, and seizures, which may be associated with a febrile illness. Basal ganglia or ectopic calcification may be found in more than 35% of patients. In addition, about 10% of patients may have absolute hypercalciuria, which may be associated with nephrocalcinosis and kidney stones in 35% of patients. Autosomal dominant hypocalcemia type 2 is due to gain-of-function mutations of the *Gα11* subunit, and these patients appear to have clinical features that are similar to type 1 patients.

Complex Syndromes Associated with Hypoparathyroidism

Hypoparathyroidism may occur as part of a complex syndrome that may be associated with either a congenital developmental anomaly or an autoimmune syndrome. The congenital developmental anomalies associated with hypoparathyroidism, which occurs in 1 in 4000 live births, include DiGeorge syndrome; the hypoparathyroidism, deafness, and renal anomalies syndrome; the Kenney-Caffey syndrome; and syndromes associated with either lymphedema or dysmorphic features and growth failure (see Table 227-1 and E-Fig. 227-1).

Polyglandular Autoimmune Hypoparathyroidism

Polyglandular autoimmune hypoparathyroidism (Chapter 212) comprises hypoparathyroidism, Addison disease, candidiasis, and two or three of the following: type 1 diabetes mellitus, primary hypogonadism, autoimmune thyroid disease, pernicious anemia, chronic active hepatitis, steatorrhea (malabsorption), alopecia (totalis or areata), and vitiligo (see Table 227-1). Antibodies directed against the adrenal, thyroid, and parathyroid glands are detected in the sera of some patients. The polyglandular autoimmune type 2 syndrome is characterized by adrenal insufficiency, type 1 diabetes mellitus, and thyroid disease and does not involve hypoparathyroidism.

Autoimmune Acquired Hypoparathyroidism

Twenty percent of patients who have acquired hypoparathyroidism in association with autoimmune hypothyroidism have autoantibodies to the extracellular domain of the CaSR (see Table 227-1 and E-Fig. 227-1). The CaSR autoantibodies do not persist: 72% of patients who have acquired hypoparathyroidism for less than 5 years have detectable CaSR autoantibodies, whereas only 14% of patients with acquired hypoparathyroidism for more than 5 years have such autoantibodies. The majority of the patients who have CaSR autoantibodies are female.

DiGeorge Syndrome

Patients with the DiGeorge syndrome (Chapter 231) suffer from neonatal hypoparathyroidism, T-cell immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth (e.g., cleft lip and/or palate). Children with DiGeorge syndrome often die from infections related to the immunodeficiency.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with hypoparathyroidism may present with symptoms and signs of acute or chronic hypocalcemia, as described above. The diagnosis requires accurate measurement of PTH. Serum concentrations of immunoreactive PTH are low or undetectable despite the presence of hypocalcemia. Concentrations of $1,25(OH)_2D_3$ are usually in the low-normal to low range, but alkaline phosphatase activity is normal (see Fig. 227-3). The daily urinary excretion of calcium may be reduced, although the fractional excretion of calcium is invariably increased.

TREATMENT

The main treatments for the hypocalcemia due to hypoparathyroidism are vitamin D preparations and supplemental calcium, as described previously.[27] After surgery or irradiation, parathyroid function often returns, but persistent hypocalcemia requires treatment with vitamin D preparations.

For primary hypothyroidism, calcitriol (0.25-1.0 μg per day) and alfacalcidol (0.25-1.0 μg per day) appear to provide equivalent results.[A7] Recombinant human PTH (1-84), (rhPTH, at 50 μg subcutaneously once daily) is useful to reduce the required doses of calcium and vitamin D as well as for patients whose hypocalcemia is refractory to treatment with vitamin D preparations and calcium supplements. Doses should be titrated every 4 weeks, with the goal of reducing oral calcium supplements to as low as 500 mg/day and to discontinue vitamin D supplements, while keeping serum calcium within the low-normal range. After a stable dose is achieved, serum calcium and phosphate levels should be monitored every 3 to 6 months and urinary calcium excretion at least yearly.

For autosomal dominant hypocalcemia, treatment with rhPTH (0.2-2.5 μg/kg/day) can ameliorate the hypocalcemia and even seizures.[28] By comparison, vitamin D and calcium supplementation to correct the hypocalcemia may worsen the hypercalciuria and lead to renal impairment.

For functional hypoparathyroidism caused by severe hypomagnesemia, magnesium chloride, 35 to 50 mmol intravenously in 1 L of 5% glucose given over 12 to 24 hours, may be repeatedly required to restore normomagnesemia. If required, oral magnesium glycerophosphate (24 mmol/day in 3 divided doses) can be continued if to maintain normocalcemia.

PSEUDOHYPOPARATHYROIDISM

Patients with pseudohypoparathyroidism, which may be inherited as an autosomal dominant disorder, are characterized by hypocalcemia and hyperphosphatemia due to resistance to PTH rather than PTH deficiency (see Table 227-6).[29]

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Five variants, which form part of a group of inactivating PTH/PTHrP signalling disorders (iPPSDs), are recognized on the basis of biochemical and somatic features (Table 227-8). Patients with PHP 1a exhibit PTH resistance (hypocalcemia, hyperphosphatemia, elevated serum PTH, and an absence of an increase in serum and urinary cAMP and urinary phosphate following intravenous human PTH infusion), together with the features of Albright hereditary osteodystrophy, which includes short stature, obesity, subcutaneous calcification, intellectual disability, round facies, dental hypoplasia, and brachydactyly (i.e., shortening of the metacarpals, particularly the third, fourth, and fifth). Patients with PHP 1b exhibit PTH resistance only and do not have the somatic features of Albright hereditary osteodystrophy, whereas patients with pseudopseudohypoparathyroidism exhibit the somatic features of Albright hereditary osteodystrophy in the absence of PTH resistance.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The absence of a normal rise in urinary excretion of cAMP after an infusion of PTH in pseudohypoparathyroidism 1a indicates a defect at some site of the PTH receptor–adenyl cyclase system (see E-Fig. 227-1). Patients with pseudohypoparathyroidism 1a may also show resistance to other hormones, such as thyroid-stimulating hormone, follicle-stimulating hormone, and luteinizing hormone. Inactivating mutations of the Gsα gene (referred to as *GNAS1*), which is located on chromosome 20q13.2, have been identified in pseudohypoparathyroidism 1a and pseudopseudohypoparathyroidism patients (see Table 227-1 and E-Fig. 227-1). Pseudohypoparathyroidism 1b is due to deletions that are located upstream of the *GNAS1* gene. Moreover, in affected individuals, the deletion involves the maternal allele, whereas its occurrence on the paternal allele results in unaffected healthy carriers. This finding is consistent with parental imprinting of the *GNAS1* abnormality causing pseudohypoparathyroidism 1b.

TREATMENT

Treatment is as for other causes of hypoparathyroidism.

228 PAGET DISEASE OF BONE

STUART H. RALSTON

DEFINITION

Paget disease of bone is a focal disorder of the skeleton characterized by increased and disorganized bone remodeling.[1] Affected bones enlarge, become deformed, and are at increased risk for pathologic fractures.

EPIDEMIOLOGY

The prevalence of Paget disease is about 0.5% in the United Kingdom and United States.[2] It also occurs in Western Europe and in people of European descent who have migrated to other parts of the world. Paget disease is rare in Scandinavians, Africans, and Asians. These differences are thought to have a genetic basis occurring as the result of founder mutations in northwest Europe many centuries ago, with subsequent spread to the remainder of the world through emigration. The incidence of Paget disease increases with age; in the United Kingdom, the incidence in women and men respectively is 0.037 to 0.074 per 10,000 person years in individuals ages 45 to 49 years but doubles in frequency each decade thereafter to reach an incidence of about 3.7 and 6.3 per 10,000 person years in individuals ages 85 years and older. The prevalence and severity of Paget disease have diminished in the United Kingdom and many countries over the past 25 years.[3] Although the mechanisms are unclear, suggested explanations include the influx of migrants from low prevalence areas, improved nutrition, a more sedentary lifestyle with a reduction in skeletal injuries, and reduced exposure to infections.

PATHOBIOLOGY

Susceptibility to Paget disease is strongly influenced by genetic factors, but environmental factors are also important. The importance of genetics is emphasized by the facts that between 5 and 40% of patients have a positive family history and that the risk for developing Paget disease in a first-degree relative of a patient is about seven-fold higher than in the general population. In many families, the disease is transmitted in an autosomal dominant manner, although penetrance is incomplete.

The most important susceptibility gene for classical Paget disease is *SQSTM1*. Mutations of *SQSTM1* are present in up to 40% of patients with a family history and 5 to 10% of people without a family history. The *SQSTM1* gene encodes a protein called p62 that is involved in regulating signal transduction downstream of the receptor activator of nuclear factor κB (RANK), which plays a critical role in regulating osteoclastogenesis when activated by RANK ligand (RANKL) (E-Fig. 228-1). The disease-causing mutations cluster in the ubiquitin-associated domain and have the effect of upregulating nuclear factor κB (NFκB) signaling and stimulating osteoclastogenesis by complex mechanisms that are reviewed in detail elsewhere.

Genome-wide association studies have identified seven other loci that predispose to Paget disease and that individually increase the risk between 1.4- and 1.7-fold.[4] These loci have additive effects, such that individuals who carry several predisposing alleles have a substantially increased risk for developing Paget disease. Many lie close to genes that play key roles in osteoclast function, including *CSF1*, which encodes macrophage colony-stimulating factor (M-CSF); *TNFRSF11A*, which encodes RANK; *TM7SF4*, which encodes DC-STAMP; *OPTN*, which encodes optineurin; *PML*, which encodes a protein involved in regulating interferon signaling; and *RIN3*, which encodes a guanine exchange factor that is expressed in osteoclasts (see E-Fig. 228-1).

Rare inherited diseases with clinical features overlapping with those of Paget disease[5] include familial expansile osteolysis and related syndromes caused by mutations affecting the signal peptide of RANK, as well as juvenile Paget disease caused by loss of function mutations affecting osteoprotegerin. Mutations in *VCP*, *hnRNPA2B1*, *hnRNPA1*, *PFN1*, *OPTN*, and *SQSMT*, which may result in defects in the autophagy pathway, can also lead to multisystem proteinopathy where

228 PAGET DISEASE OF BONE

STUART H. RALSTON

DEFINITION

Paget disease of bone is a focal disorder of the skeleton characterized by increased and disorganized bone remodeling.[1] Affected bones enlarge, become deformed, and are at increased risk for pathologic fractures.

EPIDEMIOLOGY

The prevalence of Paget disease is about 0.5% in the United Kingdom and United States.[2] It also occurs in Western Europe and in people of European descent who have migrated to other parts of the world. Paget disease is rare in Scandinavians, Africans, and Asians. These differences are thought to have a genetic basis occurring as the result of founder mutations in northwest Europe many centuries ago, with subsequent spread to the remainder of the world through emigration. The incidence of Paget disease increases with age; in the United Kingdom, the incidence in women and men respectively is 0.037 to 0.074 per 10,000 person years in individuals ages 45 to 49 years but doubles in frequency each decade thereafter to reach an incidence of about 3.7 and 6.3 per 10,000 person years in individuals ages 85 years and older. The prevalence and severity of Paget disease have diminished in the United Kingdom and many countries over the past 25 years.[3] Although the mechanisms are unclear, suggested explanations include the influx of migrants from low prevalence areas, improved nutrition, a more sedentary lifestyle with a reduction in skeletal injuries, and reduced exposure to infections.

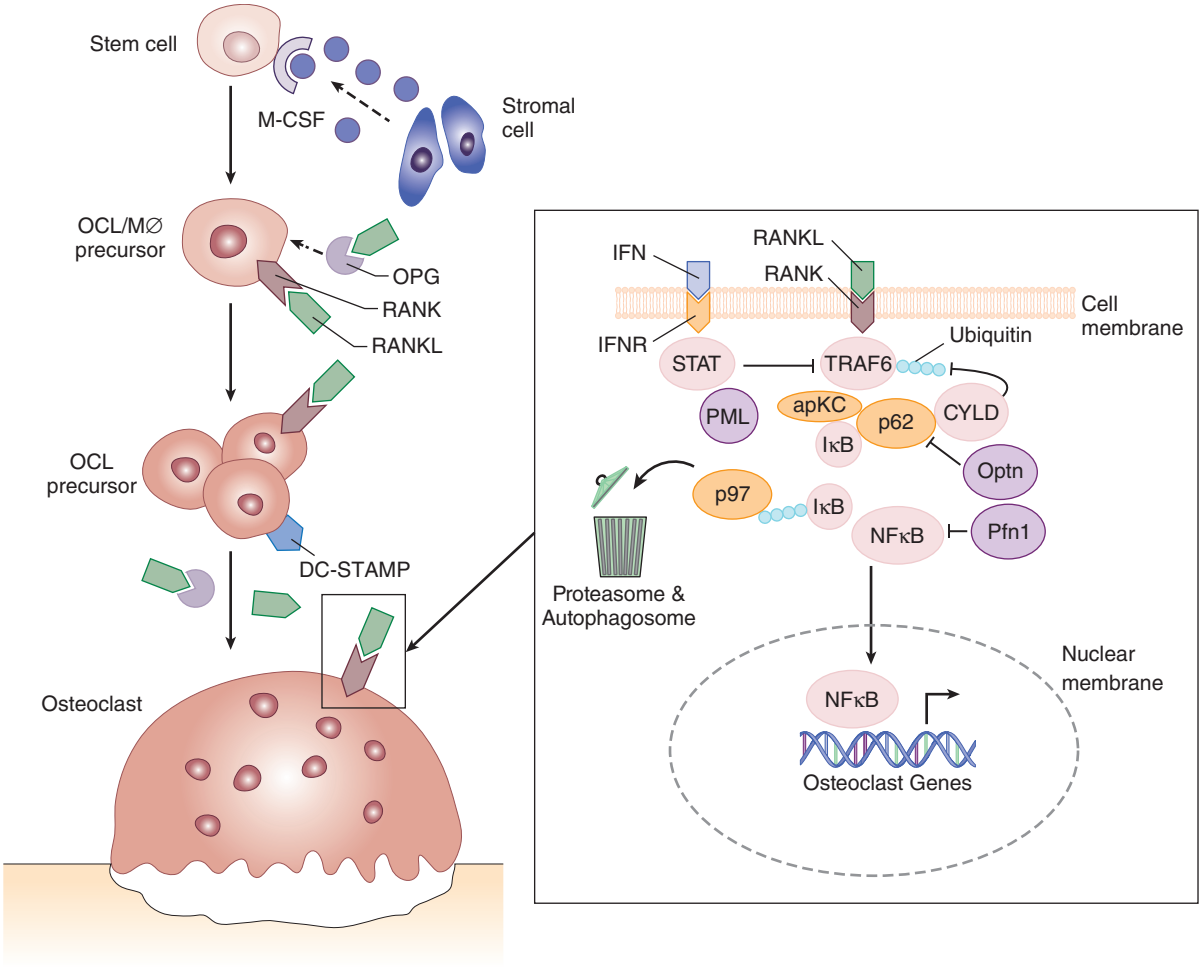
PATHOBIOLOGY

Susceptibility to Paget disease is strongly influenced by genetic factors, but environmental factors are also important. The importance of genetics is emphasized by the facts that between 5 and 40% of patients have a positive family history and that the risk for developing Paget disease in a first-degree relative of a patient is about seven-fold higher than in the general population. In many families, the disease is transmitted in an autosomal dominant manner, although penetrance is incomplete.

The most important susceptibility gene for classical Paget disease is *SQSTM1*. Mutations of *SQSTM1* are present in up to 40% of patients with a family history and 5 to 10% of people without a family history. The *SQSTM1* gene encodes a protein called p62 that is involved in regulating signal transduction downstream of the receptor activator of nuclear factor κB (RANK), which plays a critical role in regulating osteoclastogenesis when activated by RANK ligand (RANKL) (E-Fig. 228-1). The disease-causing mutations cluster in the ubiquitin-associated domain and have the effect of upregulating nuclear factor κB (NFκB) signaling and stimulating osteoclastogenesis by complex mechanisms that are reviewed in detail elsewhere.

Genome-wide association studies have identified seven other loci that predispose to Paget disease and that individually increase the risk between 1.4- and 1.7-fold.[4] These loci have additive effects, such that individuals who carry several predisposing alleles have a substantially increased risk for developing Paget disease. Many lie close to genes that play key roles in osteoclast function, including *CSF1*, which encodes macrophage colony-stimulating factor (M-CSF); *TNFRSF11A*, which encodes RANK; *TM7SF4*, which encodes DC-STAMP; *OPTN*, which encodes optineurin; *PML*, which encodes a protein involved in regulating interferon signaling; and *RIN3*, which encodes a guanine exchange factor that is expressed in osteoclasts (see E-Fig. 228-1).

Rare inherited diseases with clinical features overlapping with those of Paget disease[5] include familial expansile osteolysis and related syndromes caused by mutations affecting the signal peptide of RANK, as well as juvenile Paget disease caused by loss of function mutations affecting osteoprotegerin. Mutations in *VCP*, *hnRNPA2B1*, *hnRNPA1*, *PFN1*, *OPTN*, and *SQSMT*, which may result in defects in the autophagy pathway, can also lead to multisystem proteinopathy where



E-FIGURE 228-1. Regulators of osteoclast dysfunction in Paget disease. Some of the key molecules that have been implicated in the pathogenesis of Paget disease are illustrated. Macrophage colony-stimulating factor (M-CSF) encoded by *CSF1* is required for differentiation of stem cells to the osteoclast/macrophage (OCL/MØ) lineage. Osteoclast differentiation and activity are enhanced when RANK (encoded by *TNFRSF11A*) is activated by RANKL but inhibited by OPG (encoded by *TNFRSF11B*). Fusion of osteoclast precursors to form mature osteoclasts requires DC-STAMP (encoded by *TM7SF4*). Within the cell (*inset*), p62 (encoded by *SQSTM1*) is required for signal transduction downstream of the RANK receptor and is also involved in regulating autophagy. The p97 protein (encoded by *VCP*), Optn (encoded by *OPTN*), and Pfn1 (encoded by *PFN1*) are involved in regulating NFκB signaling and autophagy whereas *PML* acts as a mediator of interferon signaling by interacting with STAT, which negatively regulates osteoclastogenesis.

ABSTRACT

Paget disease of bone is characterized by focal abnormalities of increased and disorganized bone remodeling affecting one or more skeletal sites. It predominantly affects people of European descent and is rarely diagnosed before the age of 50 but becomes more common with increasing age. Men are affected more commonly than women. Genetic factors play an important role, and variants in the several genes have been identified that predispose to the disease by influencing osteoclast function and autophagy. Many patients are asymptomatic, but bone pain is the most common symptom in those who do come to medical attention. Other complications include deformity, pathologic fractures, deafness, osteoarthritis, nerve compression syndromes, and osteosarcoma. The diagnosis is often suspected by finding an elevated serum alkaline phosphatase or by finding typical features on a radiograph. The most sensitive imaging technique is radionuclide bone scan, which is the best way to define the extent of disease. The treatment of choice is bisphosphonates, which are indicated when bone pain is localized to an affected site. Bisphosphonates should not be prescribed with the aim of normalizing alkaline phosphatase values in asymptomatic patients. Within the bisphosphonates, zoledronic acid is most likely to give a favorable pain response and has a prolonged duration of action with effects that can persist for several years.

KEYWORDS

Paget disease of bone
osteoclast
SQSTM1
bisphosphonate

Paget disease is part of a generalized disorder in which dementia, myopathy, or amyotrophic lateral sclerosis can also occur.[6,7] Mutations in *ZNF687* cause a form of Paget disease that is accompanied by giant cell tumors. At present, the mechanisms by which *ZNF687* mutations cause this syndrome is unclear.

Bone is normally renewed and repaired in an orderly and tightly regulated fashion through the process of bone remodeling. Bone remodeling is highly abnormal in Paget disease. Osteoclasts are increased in number and size, and they are hypernucleated. Some contain nuclear inclusion bodies, which may be aggregates of undegraded proteins caused by defects in the autophagy pathway. Bone formation is markedly increased, and the amount of new bone that is formed exceeds that which is removed by osteoclastic activity, leading to enlargement and deformity of affected bones (Fig. 228-1). The newly formed bone is laid down in a disorganized fashion (woven bone) and has impaired mechanical strength. Other features include increased vascularity and marrow fibrosis.

The focal nature of Paget disease remains a puzzle. Suggested explanations include the occurrence of somatic mutations in affected bones, which locally increase osteoclast activity, or excessive mechanical loading or skeletal injuries early in life, which by causing microdamage act as a focus for localized increases in bone remodeling.

CLINICAL MANIFESTATIONS

An estimated 7 to 16% of patients with Paget disease come to medical attention, but the mode of presentation is highly variable.[8] About 20% have no symptoms; in these subjects, Paget disease is detected as the result of a raised serum alkaline phosphatase level or an abnormal radiograph in individuals who are being investigated for another reason. In the remainder, symptoms attributable to Paget disease are observed. The most common is pain, which can be due to either increased bone turnover or to a complication such as osteoarthritis (Chapter 241), spinal stenosis (Chapter 369), pseudofractures, enlarged skull, bowing of long bones, or nerve compression syndromes. Deafness, which may occur in patients with skull involvement, is usually conductive rather than due to auditory nerve compression. Osteosarcoma (Chapter 187) occurs in less than 0.5% of cases but should be suspected in patients who experience a sudden increase in bone pain or swelling of an affected site. Other, rare complications include obstructive hydrocephalus, high-output cardiac failure, and hypercalcemia in patients who are immobilized. The risk for cardiovascular disease is increased in patients with Paget disease compared with age- and gender-matched controls, probably owing to an increased prevalence of vascular calcification.

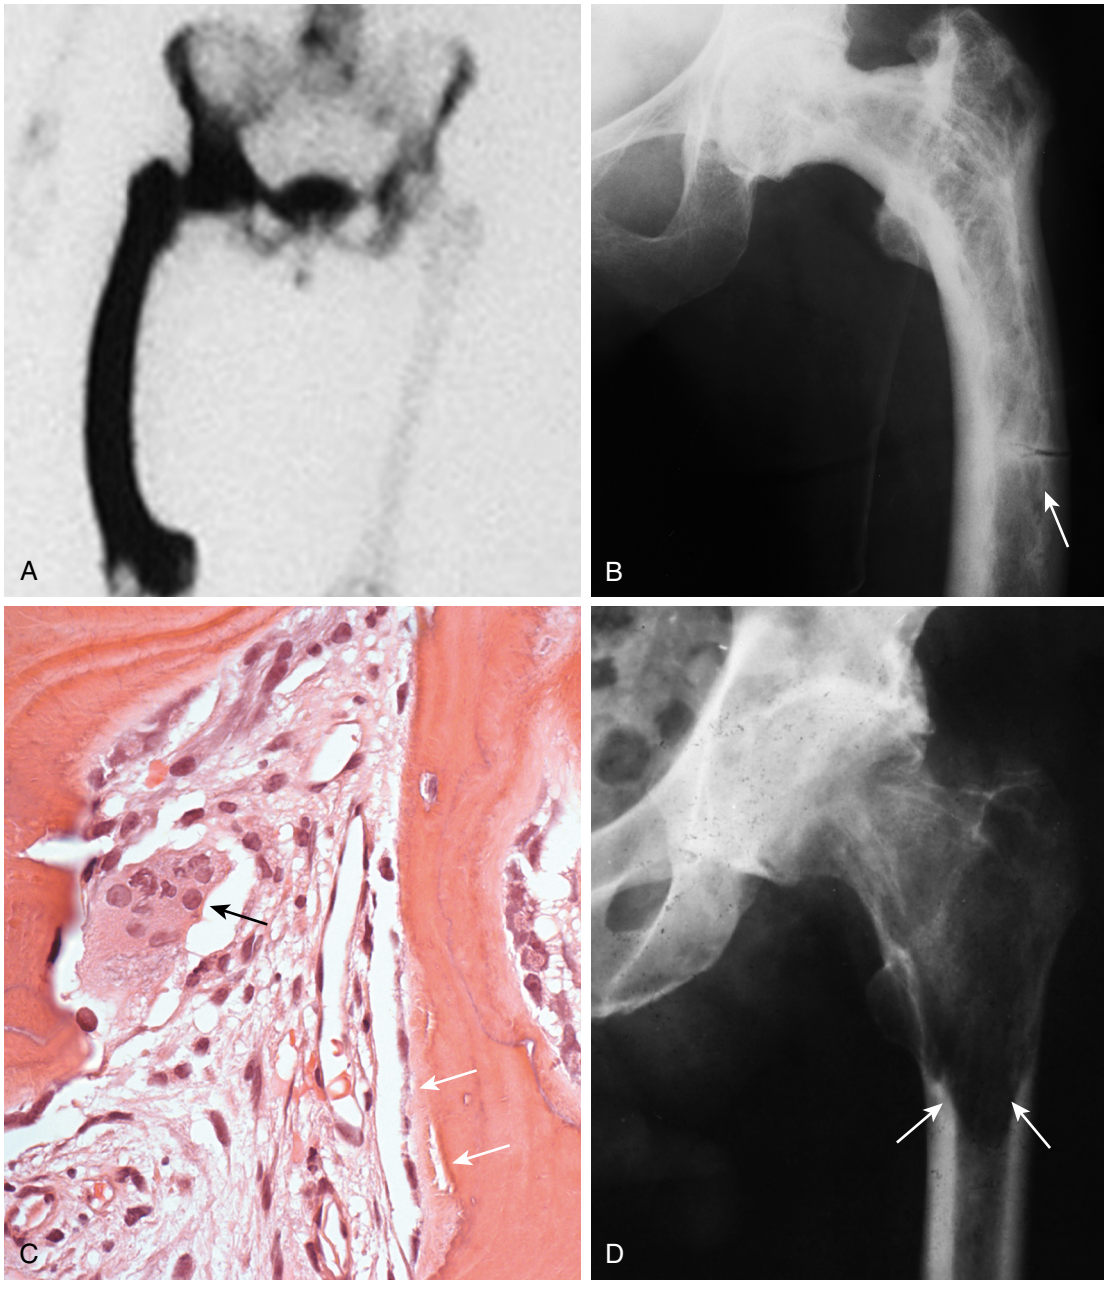


FIGURE 228-1. Radiographic and histologic features of Paget disease. A, Radionuclide bone scan image showing intense tracer uptake, typical of Paget disease of bone affecting the right femur. **B**, Radiograph of an affected left femur showing bone expansion with mixed osteolytic/osteosclerotic areas and loss of normal trabecular pattern. A pseudofracture is visible in the lateral cortex (*arrow*). **C**, Histologic features from a hematoxylin and eosin-stained section. A large osteoclast is visible (*black arrow*) close to an area of new bone formation (*white arrows*). There is extensive marrow fibrosis. Irregular cement lines typical of woven bone are apparent to the right of section. **D**, Predominantly lytic Paget disease of the left femur. The lytic area involves the intertrochanteric region and extends down the femoral shaft (*white arrows*).

Most patients have no clinical signs. However, some patients present with bone deformity (see Fig. 228-1) or warmth of the skin overlying an affected bone.

DIAGNOSIS

The diagnosis can usually be made by radiography, which shows the typical features of focal osteolysis with coarsening of the trabecular pattern, bone expansion, and cortical thickening (see Fig. 228-1).[9] Initially, the disease may be predominantly lytic in nature (see Fig. 228-1). The most sensitive way of defining the extent of Paget disease is a radionuclide bone scan in which tracer uptake is intensely increased at affected sites (see Fig. 228-1).[10] Imaging with magnetic resonance imaging and computed tomography is not usually required unless complications such as spinal stenosis or osteosarcoma are suspected.

Laboratory testing should include assessment of renal function, calcium, albumin, alkaline phosphatase, and 25(OH)D levels; liver function should be assessed to exclude the possibility that elevations in alkaline phosphatase are of hepatic origin. Typically, Paget disease presents with an elevation in alkaline phosphatase with otherwise normal biochemistries, but normal levels of alkaline phosphatase do not exclude the diagnosis. Vitamin D deficiency is a common finding but most likely reflects the fact that Paget disease predominantly affects older people in whom vitamin D deficiency is prevalent. Specialized markers such as bone-specific alkaline phosphatase or procollagen type 1 N-terminal propeptide can be useful in patients with coexisting liver disease but otherwise offer no advantage over total alkaline phosphatase for diagnosis and to assess response to the treatment. Analysis of genetic markers is being explored in the prediction of people at risk for developing Paget disease,[11] but genetic testing for susceptibility is not generally performed in routine clinical practice.

The differential diagnosis includes hyperostosis frontalis interna (a benign condition characterized by osteosclerosis of the frontal bones of the skull), fibrous dysplasia, chronic recurrent multifocal osteomyelitis (which can present with mixed osteosclerotic and osteolytic lesions), and osteosclerotic metastases, particularly from carcinoma of the prostate. Usually, Paget disease can be distinguished from these conditions clinically and through imaging, but occasionally, biopsy of an affected site may be required.

TREATMENT

The most common indication for medical treatment of Paget disease is bone pain localized to an affected site.[12] Bone pain may be caused by increased metabolic activity, but other causes may be operative, such as nerve compression syndromes, pseudofractures, secondary osteoarthritis, and other musculoskeletal conditions. Careful assessment of the patient is therefore necessary to decide on the most appropriate treatment. Bone pain caused by increased metabolic activity is localized to the affected site and is usually accompanied by a raised alkaline phosphatase level. It is common to encounter patients in whom pain occurs in the presence of coexisting osteoarthritis, bone deformity, or other musculoskeletal conditions. In such cases, it can be difficult to be sure about the origin of the pain, and many clinicians give a therapeutic trial of bisphosphonates to aid diagnosis. If the pain responds, it is assumed to be due to increased metabolic activity; if it does not, further evaluation should be undertaken to identify the cause and treat the patient appropriately. Pseudofractures, which are areas of focal osteolysis that traverse the lateral cortex of weight-bearing bones of the lower limbs, represent a distinct management problem. Some remain stable for prolonged periods without causing symptoms; others regress spontaneously; and others progress to pathologic fracture, often in association with a localized increase in pain at the affected site.

Bisphosphonates

Bisphosphonates are the drugs of first choice for the treatment of pain that is thought to be due to increased metabolic activity, and strong evidence indicates that they are more effective than placebo at improving bone pain in Paget disease (Table 228-1).[A1] Data comparing different bisphosphonates are limited, but intravenous zoledronic acid has been found to be superior to pamidronate and risedronate for lowering alkaline phosphatase level[13] and for relieving pain.

Repeated courses of bisphosphonates with the aim of normalizing alkaline phosphatase (intensive treatment) is no better in terms of pain, quality of life, or complications compared with therapy primarily aimed at controlling symptoms (symptomatic therapy).[A2] These findings demonstrate that trying to restore alkaline phosphatase to normal confers no clinical benefit over symptom-directed treatment.

After initiation of bisphosphonate therapy, levels of alkaline phosphatase start to fall within about 10 days, reach a nadir between 3 and 6 months, and can remain suppressed for many months or years thereafter, particularly with zoledronic acid.[14] Symptoms can improve while alkaline phosphatase levels are still falling, and good clinical responses are often observed in patients whose alkaline phosphatase levels are not restored to normal. Conversely, symptoms may recur before alkaline phosphatase values have become elevated again.

TABLE 228-1 BISPHOSPHONATES USED IN THE TREATMENT OF PAGET DISEASE

DRUG	DOSE	COMMON ADVERSE EFFECTS
ORAL		
Risedronate	30 mg/day orally for 2 mo	Dyspepsia, esophagitis
Alendronic acid†	40 mg/day orally for 6 mo	Dyspepsia, esophagitis
INTRAVENOUS		
Pamidronate	180 mg IV in divided doses, typically 60 mg on 3 consecutive days	Acute phase response, hypocalcemia
Zoledronic acid	5 mg IV	Acute phase response, hypocalcemia
Neridronate*	100 mg IV on 2 consecutive days	Acute phase response, hypocalcemia

*Only licensed in Italy. Can also be given intramuscularly in a dose of 25 mg daily for 8 days.
†Not licensed in the United Kingdom or Europe for Paget disease. Pamidronate and risedronate should be avoided if estimated glomerular filtration rate (eGFR) <30; zoledronic acid and alendronic acid should be avoided if eGFR <35.
IV = intravenous.

Intravenous bisphosphonates can cause transient bone pain, myalgia, headache, nausea, pyrexia, and fatigue within 1 to 3 days of the infusion in about 25% of cases (acute phase response). These symptoms can be ameliorated by acetaminophen given before and for a few days after the infusion, but they almost always subside within 7 days even without treatment. The acute phase response is much less common after second and subsequent infusions. Hypocalcemia may occur, particularly in patients with substantial elevations in bone turnover and vitamin D deficiency. The risk can be minimized by correcting vitamin D deficiency before treatment and providing calcium and vitamin D supplements for the first 1 or 2 weeks after the infusion.

Patients who take oral bisphosphonates must fast before dosing and for at least 30 minutes afterward to achieve adequate absorption. The most common adverse effect is dyspepsia. Other rare side effects of bisphosphonates include uveitis, skin rashes, atrial fibrillation, and osteonecrosis of the jaw (Chapter 229), as well as atypical subtrochanteric fractures. Bisphosphonates can cause kidney injury and are contraindicated in patients with significant renal impairment.

Other Drug Treatments

Analgesics, nonsteroidal anti-inflammatory drugs (see Table 26-4), and antineuropathic agents (e.g., amitriptyline 10 to 25 mg at bedtime or gabapentin 300 mg three times daily; see Table 26-5) may be required in patients with Paget disease, particularly when osteoarthritis or a nerve compression syndrome coexists. Calcitonin, 50 to 100 IU subcutaneously three times a week for up to 3 months can improve bone pain due to metabolic activity in Paget disease but is seldom used except in patients for whom bisphosphonates are contraindicated; adverse effects such as nausea and flushing can be problematic, and resistance may develop owing to the formation of neutralizing antibodies.

Nonpharmacologic Treatments

Nonpharmacologic approaches (e.g., acupuncture, physiotherapy, hydrotherapy, and transcutaneous electrical nerve stimulation) are often used to control pain, but their effectiveness has not been documented in controlled trials. Clinical experience suggests that specific problems such as limb shortening and deformity can be helped by aids and devices such as walking sticks and shoe raises.

Monitoring Disease Activity and the Effects of Treatment

Metabolic activity and the response to treatment are typically assessed by measuring the alkaline phosphatase level, but levels can be normal in patients with localized disease that is metabolically active. Further courses of treatment should be considered in patients who have recurrent or persistent pain and in whom alkaline phosphatase levels remain or become elevated.

Surgery

Orthopedic surgery may be required for the management of coexisting osteoarthritis, pseudofractures, fractures, bone deformity, and spinal stenosis. Osteotomy is performed infrequently, but small case series have reported good results. Surgery is much more frequently required to repair fractures and

to replace joints that are affected by osteoarthritis.[15] Although surgical treatment can be technically challenging because of deformity, osteosclerosis, and increased vascularity, the results of surgery are generally very good, and evidence from case series indicate that fractures through Pagetic bone generally heal normally. Bisphosphonates may be given before orthopedic and spinal surgery with the aim of reducing operative blood loss, but evidence to suggest that this approach actually reduces blood loss is limited. Orthopedic surgery may also be required in patients who develop osteosarcoma, but the prognosis is poor even with aggressive operative treatment. Cochlear implantation can benefit patients with deafness owing to Paget disease of the skull.

PROGNOSIS

The prognosis of Paget disease is highly variable. Some patients remain completely asymptomatic throughout life, but patients who present clinically frequently have complications and have a significant reduction in quality of life. Although modern bisphosphonates are highly effective at suppressing bone turnover in Paget disease, they have not as yet been shown to alter the natural history of the disease or prevent complications. The severity and extent of disease can be predicted by genotyping for *SQSTM1* mutations and other risk alleles, and studies are currently in progress to determine whether genetic testing can be combined with prophylactic bisphosphonate therapy to prevent or delay the onset of disease.

229 OSTEONECROSIS, OSTEOSCLEROSIS/ HYPEROSTOSIS, AND OTHER DISORDERS OF BONE

MICHAEL P. WHYTE AND KATHRYN M. DAHIR

OSTEONECROSIS

DEFINITION

Osteonecrosis (aseptic, avascular, or ischemic necrosis of bone) refers to skeletal infarction. Bone infarcts may be asymptomatic, cause self-limited discomfort, or engender painful collapse of subarticular bone and resulting joint destruction.

EPIDEMIOLOGY AND PATHOBIOLOGY

Many conditions are associated with osteonecrosis (Table 229-1). In adults, the most common causes are prior hip fracture, osteomyelitis (Chapter 251), renal dialysis (Chapter 117), ethanol abuse (Chapter 364), and long-term glucocorticoid therapy (Chapter 28).[1]

Skeletal infarction can result from blood vessel destruction (e.g., joint dislocation, fracture), obstruction (e.g., thromboemboli, sickle cell disease, fat emboli, caisson disease), or, hypothetically, compression from local expansion of fatty tissue (e.g., ethanol abuse, glucocorticoid treatment, diabetes mellitus). However, symptoms may not occur unless, weeks later, resorption of dead bone during skeletal repair leads to pathologic fracture. Certain skeletal sites (often subarticular) are predisposed to osteonecrosis, but the locations differ for traumatic compared with nontraumatic processes. Osteochondrosis refers to necrosis of ossification centers. At all ages, however, the femoral head is especially prone to infarction. Nontraumatic osteonecrosis commonly affects the humeral head, femoral condyles, distal end of the tibia, and talus. Although the pathogenesis is uncertain, administration of potent bone antiresorptive agents, especially to patients with malignant disease, and antiangiogenic agents has been associated with osteonecrosis of the jaw (Fig. 229-1).[2,3]

CLINICAL MANIFESTATIONS

Pain occurs acutely if there is skeletal collapse. Chronic arthralgia results from desquamated necrotic tissue and articular destruction.

DIAGNOSIS

Magnetic resonance imaging that demonstrates bone marrow edema is especially sensitive for detecting early osteonecrosis.[4] Bone scintigraphy discloses skeletal reconstitution with or without fracture. Relatively late in the pathologic process, radiographs first show patchy areas of osteopenia and osteosclerosis that reflect skeletal repair. A linear subchondral radiolucency (crescent sign) indicates bone collapse.

229 OSTEONECROSIS, OSTEOSCLEROSIS/ HYPEROSTOSIS, AND OTHER DISORDERS OF BONE

MICHAEL P. WHYTE AND KATHRYN M. DAHIR

OSTEONECROSIS

DEFINITION

Osteonecrosis (aseptic, avascular, or ischemic necrosis of bone) refers to skeletal infarction. Bone infarcts may be asymptomatic, cause self-limited discomfort, or engender painful collapse of subarticular bone and resulting joint destruction.

EPIDEMIOLOGY AND PATHOBIOLOGY

Many conditions are associated with osteonecrosis (Table 229-1). In adults, the most common causes are prior hip fracture, osteomyelitis (Chapter 251), renal dialysis (Chapter 117), ethanol abuse (Chapter 364), and long-term glucocorticoid therapy (Chapter 28).[1]

Skeletal infarction can result from blood vessel destruction (e.g., joint dislocation, fracture), obstruction (e.g., thromboemboli, sickle cell disease, fat emboli, caisson disease), or, hypothetically, compression from local expansion of fatty tissue (e.g., ethanol abuse, glucocorticoid treatment, diabetes mellitus). However, symptoms may not occur unless, weeks later, resorption of dead bone during skeletal repair leads to pathologic fracture. Certain skeletal sites (often subarticular) are predisposed to osteonecrosis, but the locations differ for traumatic compared with nontraumatic processes. Osteochondrosis refers to necrosis of ossification centers. At all ages, however, the femoral head is especially prone to infarction. Nontraumatic osteonecrosis commonly affects the humeral head, femoral condyles, distal end of the tibia, and talus. Although the pathogenesis is uncertain, administration of potent bone antiresorptive agents, especially to patients with malignant disease, and antiangiogenic agents has been associated with osteonecrosis of the jaw (Fig. 229-1).[2,3]

CLINICAL MANIFESTATIONS

Pain occurs acutely if there is skeletal collapse. Chronic arthralgia results from desquamated necrotic tissue and articular destruction.

DIAGNOSIS

Magnetic resonance imaging that demonstrates bone marrow edema is especially sensitive for detecting early osteonecrosis.[4] Bone scintigraphy discloses skeletal reconstitution with or without fracture. Relatively late in the pathologic process, radiographs first show patchy areas of osteopenia and osteosclerosis that reflect skeletal repair. A linear subchondral radiolucency (crescent sign) indicates bone collapse.

ABSTRACT

Osteonecrosis is ischemic bone infarction, which can range in severity from being asymptomatic to painful collapse of bone or joint destruction. Nontraumatic osteonecrosis typically affects the humeral head, femoral condyles, distal end of the tibia, or talus. Surgical procedures, such as decompression, arthrotomy, or resection, may limit disability. Osteonecrosis of the jaw can be a severe adverse event associated with the use of potent antiresorptive agents. Many conditions are associated with radiographic evidence of focal or generalized increase in bone density. Among these, osteosclerosis refers to thickening of trabecular bone, whereas hyperostosis describes widening of cortical bone. Medical therapy for most of these disorders is unsatisfactory.

KEYWORDS

osteonecrosis
osteopetrosis
fibrous dysplasia
exostosis
achondroplasia
hyperostosis
osteosclerosis
aseptic necrosis

TREATMENT

Nonweight bearing is advisable for the affected limb. Decompression by trephine insertion is used at some sites. Arthrotomy to remove debris, transpositional osteotomy, arthroplasty, or joint replacement may be necessary.[5] Medical approaches to osteonecrosis of the jaw have been disappointing,[A1,6] but teriparatide (an osteoanabolic parathyroid analogue given under expert supervision) may lead to resolution in about 60% of cases when the condition is diagnosed in its early stages.[7] Surgical resection also can be beneficial.[8]

OSTEOSCLEROSIS/HYPEROSTOSIS

Osteosclerosis refers to thickening of trabecular (spongy, cancellous) bone.[9] Hyperostosis describes widening of cortical (compact) bone. Many conditions are associated with radiographic evidence of increased bone density (Table 229-2). Skeletal dysplasias, metabolic disturbances, and various other disorders can cause generalized or focal increases in bone mass. Aberrations in skeletal growth, modeling (shaping), or remodeling (turnover) may be at fault. Increases in trabecular bone, cortical bone, or both may augment skeletal density. Most of the dysplasias can be diagnosed by gene mutation analysis.

TABLE 229-2 DISORDERS THAT CAUSE DENSE BONES

DYSPLASIAS
Central osteosclerosis with ectodermal dysplasia
Craniodiaphyseal dysplasia
Craniometaphyseal dysplasia
Dysosteosclerosis
Endosteal hyperostosis
van Buchem disease
Sclerosteosis (types 1 and 2)
Worth type (LRP5 and LRP6 activation)
Frontometaphyseal dysplasia
Infantile cortical hyperostosis (Caffey disease)
Juvenile Paget disease
Lenz-Majewski syndrome
Melorheostosis
Metaphyseal dysplasia (Pyle disease)
Mixed sclerosing bone dystrophy
Oculodento-osseous dysplasia
Osteodysplasia of Melnick and Needles
Osteopathia striata
Osteopetrosis (multiple types)
Osteopoikilosis
Progressive diaphyseal dysplasia (Engelmann disease)
Pyknodysostosis
Trichodentoosseous dysplasia
METABOLIC CONDITIONS
Carbonic anhydrase II deficiency
Heavy metal poisoning
Hepatitis C–associated osteosclerosis
Hyperparathyroidism, hypoparathyroidism, pseudohypoparathyroidism
Hypervitaminosis A, D
Hypophosphatemic rickets or osteomalacia (several types)
Milk-alkali syndrome
Renal osteodystrophy
Skeletal fluorosis (endemic and nonendemic)
OTHER DISORDERS
Axial osteomalacia
Erdheim-Chester disease
Fibrogenesis imperfecta ossium
Ionizing radiation
Lymphoma
Mastocytosis
Multiple myeloma
Myelofibrosis
Osteomyelitis
Osteonecrosis
Paget bone disease
Sarcoidosis
Skeletal metastases
Tuberous sclerosis

OSTEOSCLEROSIS

Neoplastic, hematologic, and metabolic disorders may preferentially sclerose trabecular bone because it houses marrow and remodels more rapidly than cortical bone.

FIBROGENESIS IMPERFECTA OSSIUM

This rare, usually sporadic condition features generalized osteopenia, but coarsening of the remaining trabeculae places it among the disorders that manifest osteosclerosis. The cause is unknown, but it is possibly genetic.[10] Subperiosteal bone formation and collagen synthesis in nonosseous tissues seem to be normal.

CLINICAL MANIFESTATIONS

Intractable skeletal pain typically begins gradually during middle age or later and then rapidly increases, with a debilitating course and eventual immobility. Spontaneous fractures are a prominent complication. Physical examination reveals marked bone tenderness.

DIAGNOSIS AND TREATMENT

On radiography, only the skull is spared. Initially, osteopenia and a slightly abnormal appearance of trabecular bone are noted. The skeletal lesion is a localized form of osteomalacia (Chapter 226) that varies considerably in severity from area to area.

Corticomedullary junctions become indistinct as compact bone is replaced by an abnormal cancellous pattern. Generalized osteopenia causes the remaining spongy bone to appear coarse and dense in a fishnet pattern of mixed lytic and sclerotic areas. Alkaline phosphatase activity in serum is increased. Therapy with recombinant growth hormone under expert guidance may provide short-term benefit.

HYPEROSTOSIS

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN DISEASE)

Progressive diaphyseal dysplasia, which affects all races, is inherited as an autosomal dominant trait with variable expressivity. New bone formation gradually envelops both the periosteal and endosteal surfaces of long bone diaphyses.[11] In patients with severe disease, osteosclerosis also affects the axial skeleton.

Mutations alter the gene that encodes transforming growth factor-β1. The differentiation of osteoclasts may be deranged.

CLINICAL MANIFESTATIONS

During childhood, limping or a broad-based, waddling gait is noted. Muscular dystrophy can be diagnosed erroneously. Severely affected individuals may have a characteristic body habitus featuring an enlarged head with a prominent forehead, proptosis, and thin limbs with little subcutaneous fat or muscle mass as well as tender, thickened bones. Cranial nerve palsies and raised intracranial pressure can occur. Some patients have hepatosplenomegaly and Raynaud phenomenon. Symptoms may remit after puberty.

DIAGNOSIS

Irregular hyperostosis of the diaphyses of the major long bones slowly develops as a result of periosteal and endosteal new bone formation. The femur and tibia are most commonly affected. Metaphyses may be involved. The age at onset, rate of progression, and severity are variable. Clinical, radiographic, and bone scan findings are generally concordant. Serum alkaline phosphatase activity, biochemical markers of skeletal turnover, and erythrocyte sedimentation rate may be elevated. Histopathologic study reveals newly formed woven bone that matures and becomes incorporated into cortical bone. Electron microscopy of muscle may show myopathic changes and vascular abnormalities.

TREATMENT

Glucocorticoid therapy (optimally the lowest effective dose of prednisone on alternate days) can relieve bone pain and may normalize skeletal histology. Bisphosphonates or losartan under expert guidance may sometimes be useful.

ENDOSTEAL HYPEROSTOSIS

Sclerosteosis types 1 and 2 and van Buchem disease are rare autosomal recessive disorders and the most severe forms of endosteal hyperostosis. Sclerosteosis is caused by deactivating mutations in genes *SOST* and *LRP4*. Van Buchem disease involves a deletion downstream of an *SOST* enhancer. Increased osteoblastic

activity from impaired sclerostin action, with failure of osteoclasts to compensate for the increased bone formation, leads to the skeletal changes.[12]

CLINICAL MANIFESTATIONS

Sclerosteosis (generalized hyperostosis with syndactyly) affects primarily people of Dutch ancestry. The gender distribution appears equal. Patients are tall and heavy beginning in childhood, with a prominent, square mandible. Raised intracranial pressure and headache may reflect a diminishing cranial cavity that shortens life expectancy. Van Buchem disease causes progressive asymmetrical enlargement of the jaw during puberty. Patients may be symptom free, or, beginning as early as infancy, they may have recurrent facial nerve palsy, deafness, and optic atrophy from narrowing of cranial foramina. Long bones may hurt with applied pressure but are strong.

DIAGNOSIS

In sclerosteosis, the skeleton is radiographically normal in early childhood. Congenital syndactyly involves soft tissues and bone in type 1 versus 2, respectively. Progressive bone thickening widens the skull and causes prognathism. Osteosclerosis also involves the skull base, facial bones, vertebrae, pelvis, and ribs. Periosteal and especially endosteal thickening widens diaphyseal cortices and narrows medullary canals. Computed tomography can show fusion of ossicles and narrowing of the internal auditory canals and cochlear aqueducts. Serum alkaline phosphatase activity can be increased from enhanced bone formation.

TREATMENT

Management may include surgical correction of syndactyly and mandibular overgrowth. Decompression of narrowed foramina may alleviate cranial nerve palsies. Craniectomy may become necessary.

PACHYDERMOPERIOSTOSIS

Pachydermoperiostosis (hypertrophic osteoarthropathy, primary or idiopathic) features clubbing of the digits, hyperhidrosis with thickening of the skin (especially of the face), and periosteal new bone formation, most prominently in the distal ends of the limbs. Not all patients manifest all three principal features. Loss-of-function mutations are found in the *HPGD* gene that encodes 15-hydroxyprostaglandin dehydrogenase and in the *SLCO2A1* gene in the autosomal recessive forms. Autosomal dominant inheritance is also recognized.

CLINICAL MANIFESTATIONS

Men seem more severely affected than women, and Blacks more commonly than Whites. Symptoms typically begin during adolescence, intensify during the next decade, but then become quiescent. Arthralgia and fatigue are common. Stiffness and limited mobility occur in both the appendicular and the axial skeleton. Clubbing, with slowly progressive enlargement of the hands and feet, results in a pawlike appearance. Cutaneous changes include thickening, furrowing, pitting, and oiliness, especially of the scalp and face.

DIAGNOSIS

Periostitis thickens the distal portions of the tibia, fibula, radius, and ulna. Clubbing is obvious, and acro-osteolysis can occur. Periosteal proliferation is exuberant, with an irregular texture, and it often involves the epiphyses, whereas secondary hypertrophic osteoarthropathy (pulmonary or otherwise) typically causes a smooth and undulating periosteal reaction. Ankylosis of the joints, especially in the hands and feet, may trouble older patients. Bone scanning reveals symmetrical regular uptake along the cortical margins of long bones, especially in the legs—the double stripe sign. Genetic testing can diagnose hereditary forms.

TREATMENT

Patients with painful synovial effusions may respond to nonsteroidal anti-inflammatory drugs. Contractures or neurovascular compression by osteosclerotic lesions may require surgical intervention.

OSTEOSCLEROSIS WITH HYPEROSTOSIS

OSTEOPETROSIS

DEFINITION

Osteopetrosis (marble bone disease) is a group of rare disorders featuring elevated bone mass owing to lack of osteoclast formation or action during growth.[13] The two classic clinical categories are the autosomal recessive or "malignant" type, which often results in death by early childhood if untreated, and the autosomal dominant or "benign" type (Albers-Schönberg disease), which causes lesser complications. Autosomal recessive types can also feature intermediate severity, neuronal storage disease, or renal tubular acidosis with cerebral calcification owing to deficiency of carbonic anhydrase II. Bisphosphonate-induced osteopetrosis has been reported.

PATHOBIOLOGY

The defective *CLCN7* gene causing autosomal dominant osteopetrosis encodes a chloride channel that is important for osteoclasts to release hydrochloric acid. Biallelic mutations in this gene, or ones that encode components of a vacuolar hydrogen ion (H^+) pump, result in malignant osteopetrosis. Carbonic anhydrase II deficiency is caused by deactivating mutations in the gene *CA2* that encodes this isoenzyme. Especially rare autosomal recessive cases involve deficient osteoclastogenesis from loss-of-function mutations within the genes for either receptor activator of nuclear factor κB (RANK) or its ligand (RANKL).

Histopathologic studies show that all true forms of osteopetrosis feature profound deficiency of osteoclast action. Bone-embedded primary spongiosa (calcified cartilage deposited during endochondral bone formation) persists away from growth plates and is the pathognomonic finding. Defective endosteal bone remodeling impairs the formation of marrow space. Quiescent skeletal turnover leads to bone fragility from diminished interconnection of osteons, delayed conversion of immature (woven) bone to mature (compact) bone, and failure of microcracks to heal. Neuronal storage disease (ceroid-lipofuscin) may reflect a lysosomal defect. Deficient superoxide production (necessary for bone resorption) has been considered a pathogenetic factor.

CLINICAL MANIFESTATIONS

Malignant osteopetrosis can present during infancy as nasal "stuffiness" from underdeveloped mastoid and paranasal sinuses. Small cranial foramina may cause optic, oculomotor, or facial nerve palsy. Failure to thrive, delayed dentition, and fractures are common. Hypersplenism and recurrent infection, bruising, and bleeding reflect myelophthisis. Short stature, large head, frontal bossing, nystagmus, hepatosplenomegaly, and genu valgum are characteristic physical findings. Untreated children usually die during the first decade of life of hemorrhage, pneumonia, severe anemia, or sepsis.

Benign osteopetrosis can cause fracture, facial palsy, deafness, mandibular osteomyelitis, bone marrow failure, impaired vision, psychomotor delay, carpal tunnel syndrome, or osteoarthritis. Carbonic anhydrase II deficiency can lead to failure to thrive, fracture, developmental delay, mental subnormality, short stature, and cerebral calcification, but defective skeletal modeling and osteosclerosis may resolve. Both proximal and distal renal tubular acidosis have been described.

DIAGNOSIS

A generalized increase in bone density is the radiographic hallmark of osteopetrosis. In severe disease, modeling defects in long bones produce an "Erlenmeyer flask" deformity (Fig. 229-2). The cranium is usually thickened and dense, especially at the base, and the paranasal and mastoid sinuses are underpneumatized. Skeletal scintigraphy can disclose fractures and osteomyelitis. Magnetic resonance imaging helps monitor the response to bone marrow transplantation.

Serum levels of acid phosphatase and creatine kinase (brain isoenzyme) are often increased. In malignant osteopetrosis, hypocalcemia with secondary hyperparathyroidism and elevated serum concentrations of calcitriol can accompany radiographic changes of rickets. In benign osteopetrosis, biochemical indices of mineral homeostasis are typically unremarkable, although serum parathyroid hormone and lactate dehydrogenase isoenzyme levels may be elevated. Most forms of osteopetrosis can now be diagnosed by mutation analysis.

TREATMENT

Because the molecular pathogenesis, prognosis, and treatment of the more than 10 types of osteopetrosis can differ, precise diagnosis is crucial. For malignant forms of osteopetrosis, prompt use of human leukocyte antigen–identical bone marrow transplantation to supply functional osteoclasts has remarkably benefited some children. Interferon gamma 1b under expert supervision can delay the progression of malignant osteopetrosis. Calcium-deficient diets have uncertain efficacy and may be limited by hypocalcemia and rickets. Hyperbaric oxygenation helps treat osteomyelitis. Surgical decompression of optic and facial nerves can be beneficial.

FIGURE 229-2. Osteopetrosis. Anteroposterior radiograph of the distal femur shows a widened metadiaphyseal region, with alternating dense and lucent bands that are characteristic of autosomal dominant osteopetrosis. (From Whyte MP, Murphy WA. Osteopetrosis and other sclerosing bone disorders. In: Avioli LV, Krane SM, eds. *Metabolic Bone Disease*. 2nd ed. Philadelphia: WB Saunders; 1990.)

DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS

This condition is discussed in Chapter 252.

PYKNODYSOSTOSIS

This autosomal recessive condition is caused by loss-of-function mutations in *CTSK*, the gene that encodes cathepsin K. Consequently, bone collagen degradation and skeletal turnover are diminished. In chondrocytes and osteoblasts, inclusions have been described.

CLINICAL MANIFESTATIONS

Characteristic features seen during infancy or early childhood include a relatively large cranium, fronto-occipital prominence, proptosis, bluish sclerae, beaked and pointed nose, small facies and chin, obtuse mandibular angle, high-arched palate, dental malocclusion with retention of primary teeth, and disproportionate short stature. Cranial sutures remain open. Fingers are short and clubbed from acro-osteolysis or aplasia of the terminal phalanges, and the hands are small and square. Repeated fractures cause a knock-knee deformity. Mental retardation occurs in approximately 10% of patients. Adult height ranges from 4 feet 3 inches to 4 feet 11 inches. Life expectancy can be shortened by sleep apnea, recurrent respiratory infections, and right-sided heart failure from chronic upper airway obstruction secondary to micrognathia.

DIAGNOSIS

Osteosclerosis is uniform, first becoming apparent in childhood and increasing with age. Skeletal modeling defects do not distort the shaping of long bones, but they appear to have thick cortices because of narrow medullary canals. Clavicles are gracile and hypoplastic at their lateral segments. The calvarium and skull base are sclerotic, orbital ridges are dense, and wormian bones are present.

TREATMENT

Administration of growth hormones (Chapter 205) may improve growth somewhat. About 50% of patients may require treatment for sleep apnea (Chapter 394).[14] Fractures of the long bones usually mend satisfactorily. Internal fixation of long bones is formidable because of their narrow medullary space and hardness. Tooth extraction is difficult. Osteomyelitis of the mandible may require antibiotic, surgical, or hyperbaric therapy.

HEPATITIS C–ASSOCIATED OSTEOSCLEROSIS

Rarely, achy and tender limbs develop in individuals infected with hepatitis C virus (Chapter 135). Radiographic studies reveal a marked generalized increase in bone mass from osteosclerosis and hyperostosis. Disturbances in the insulin-like growth factor system may explain the enhanced bone formation. Treatment focuses on effective management of the viral infection (see Chapter 135). If needed, calcitonin or bisphosphonate therapy under expert supervision can slow bone turnover.

FOCAL OSTEOSCLEROSIS/HYPEROSTOSIS

OSTEOPOIKILOSIS

Osteopoikilosis ("spotted bones") is generally a radiographic curiosity due to a highly penetrant autosomal dominant deactivating mutation of the *LEMD3* gene. The bone lesions are usually asymptomatic. However, incorrect diagnosis may lead to confusion with serious conditions, including metastatic disease.[15] Some patients have connective tissue nevi called dermatofibrosis lenticularis disseminata (or Buschke-Ollendorff syndrome). On radiologic examination, numerous small, round or oval foci of bone sclerosis appear in cancellous bone in the metaepiphyseal regions of tubular, tarsal, carpal, and pelvic bones.

OSTEOPATHIA STRIATA

Osteopathia striata is usually an autosomal dominant curiosity of asymptomatic linear striations in the metaphyseal regions of long bones and in the ilium. However, two clinically important X-linked dominant disorders with osteopathia striata affect predominantly females: osteopathia striata with cranial sclerosis due to mutation of the *WTX* gene and osteopathia striata with widespread linear areas of dermal hypoplasia and various bone defects in the limbs due to mutation of the *PORCN* gene (Goltz syndrome).

MELORHEOSTOSIS

Melorheostosis is an ultra rare and sporadic disorder that features focal, dense bone changes, typically in the limbs and often with the appearance of dripping candle wax. Postzygotic mosaicism involving *KRAS*, *MAP2K1*, or *SMAD3* mutations has been implicated.[16]

CLINICAL MANIFESTATIONS

Involvement of a single limb is usual, and bilateral disease is generally asymmetrical.[17] Cutaneous changes over affected bones are common (e.g., linear scleroderma-like areas and hypertrichosis) and often appear before the hyperostosis. Symptoms typically begin during childhood, with pain and stiffness as the major complaints. Joints may become contracted and deformed from ectopic bone. Leg-length inequality results from soft tissue contractures and premature fusion of epiphyses. Skeletal changes seem to progress most rapidly throughout childhood. During adult life, melorheostosis may or may not gradually spread, but pain is especially common.

DIAGNOSIS

Irregular, dense, eccentric periosteal and endosteal hyperostosis affects a single bone or several adjacent bones. The lower limbs are most commonly involved. Endosteal thickening predominates during infancy and childhood, and periosteal new bone formation is prominent during adulthood. Ectopic bone formation may occur, particularly near joints.

TREATMENT

Surgical correction of contractures may be helpful.

MIXED SCLEROSING BONE DYSTROPHY

Mixed sclerosing bone dystrophy is typically a sporadic disorder with enigmatic combinations of osteopoikilosis, osteopathia striata, melorheostosis, cranial sclerosis, and other skeletal aberrations in one individual. Complications derive from the specific types of osteosclerosis or hyperostosis, such as nerve palsy with cranial sclerosis and bone pain with melorheostosis.

OTHER DISORDERS OF BONE

FIBROUS DYSPLASIA

Fibrous dysplasia is a sporadic developmental disorder with one or more expansile fibrous lesions within bone. Polyostotic disease is typically seen before the age of 10 years; monostotic disease begins in adolescence or early adulthood. McCune-Albright syndrome refers to polyostotic fibrous dysplasia, café au lait spots (Fig. 229-3), and endocrine hyperfunction.

FIGURE 229-3. McCune-Albright syndrome. Typical rough-border ("coast of Maine") pigmented café au lait spots. (From Whyte MP. Metabolic and dysplastic disorders. In: Coe FL, Favus MJ, eds. *Disorders of Bone and Mineral Metabolism*. New York: Raven Press; 1992.)

FIGURE 229-4. Fibrous dysplasia. A characteristic expansile lesion with a ground-glass appearance has caused thinning of the cortex in the mid-diaphysis of the fibula. (From Whyte MP. Fibrous dysplasia. In: Favus MJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*. 3rd ed. Philadelphia: Lippincott-Raven; 1996.)

PATHOBIOLOGY

Fibrous dysplasia and McCune-Albright syndrome (also see Chapters 205 and 212) are caused by postzygotic mosaicism of an activating mutation in the gene that encodes the α subunit of the receptor subunit/adenylate cyclase–coupling G protein, *GNAS*. Bone formation is imperfect because mesenchymal cells do not fully differentiate into osteoblasts.

CLINICAL MANIFESTATIONS

Monostotic fibrous dysplasia is more common than polyostotic disease. The skull and long bones are affected most often. The skeletal lesions can deform bones, cause fractures, and occasionally entrap nerves. Sarcomatous degeneration is rare (<1%) but typically occurs within the facial bones or femur and is more frequent with polyostotic disease. Pregnancy may reactivate quiescent lesions. McCune-Albright syndrome usually causes pseudo-precocious puberty in girls (Chapter 214) but less commonly in boys. Patients may also develop thyrotoxicosis, Cushing disease, hyperprolactinemia, or hyperparathyroidism. Excess growth hormone can be associated with more severe skeletal lesions.[18] In some patients, acquired renal phosphate wasting causes hypophosphatemic rickets or osteomalacia (see Chapters 205 and 227).

In mild disease, bone lesions may not expand. In severe cases, defects can progress and new ones may appear. Spontaneous healing does not occur, but pathologic fractures generally mend well.

DIAGNOSIS

The skeletal lesions have a characteristic radiographic appearance. In the long bones, either the metaphysis or diaphysis typically is well defined with thin cortices and a ground-glass appearance (Fig. 229-4). With aging, the defects can become lobulated, with trabeculated areas of radiolucency.

TREATMENT

Stress fractures can be difficult to detect and to treat. When the skull is involved, nerve compression may require surgical intervention. In McCune-Albright syndrome, pharmacologic control of associated endocrinopathies is important. Bisphosphonate therapy under expert supervision can sometimes be helpful, especially for bone pain.[19]

HEREDITARY MULTIPLE EXOSTOSES

This relatively common, highly penetrant, autosomal dominant disorder features irregular bone excrescences that protrude from expanded metaphyses. Mutations have been identified in the *EXT1*, *EXT2*, and *TRPS1* genes. Osteocartilaginous exostoses arise from growth plates and increase in size until linear growth ceases. Lesions, which may become detached from the parent bone, have a relatively unremarkable structure, with an outer cortex and an inner spongiosa. Disability results primarily from discrepancies in limb length when linear bone growth suffers at the expense of transverse expansion. Compression of nerves, the spinal cord, or the vascular system occurs occasionally. Sarcomatous degeneration (0.5 to 2% of patients) should be suspected when an exostosis enlarges rapidly, especially in an adult. Troublesome lesions can be resected.

ENCHONDROMATOSIS (DYSCHONDROPLASIA, OLLIER DISEASE)

This sporadic disorder features cartilaginous masses that arise from growth plates and localize within the trabecular bone. Ollier disease is caused by somatic mosaic mutations in the *IDH1* and *IDH2* genes. The disease begins with localized swelling in childhood and interferes with linear bone growth. After puberty, cartilaginous masses no longer expand, but these lesions can be replaced by mature bone. Enchondromas appear radiographically as lucent defects in flat bones or in metaphyses of tubular bones, often with central calcific stippling. When enchondromatosis occurs together with multiple hemangiomas (Maffucci syndrome), a malignancy will develop in about 50% of affected individuals.[20]

ACHONDROPLASIA

Chondrodystrophies, which are disorders of cartilage growth, result in disproportionate short stature. Achondroplasia is the most common.[21] A gain-in-function mutation occurs in the gene that encodes fibroblast growth factor receptor type 3; 80% of cases represent new autosomal dominant mutations, which are more prevalent with increasing paternal age. Short tubular bones form because of abnormal endochondral ossification in the limbs. In the chondrocranium, membranous ossification is undisturbed, so the skull vault is normal. However, the cranial base and foramen magnum are small. The head is large, with frontal bossing and midface hypoplasia. Lumbar lordosis is greatly exaggerated, and the spinal canal narrows from the upper to lower segments of the vertebral column. Radiography shows a decreasing interpediculate distance. Trunk length is relatively normal, but the limbs show rhizomelic shortening, and the hands have a trident configuration. The long bones appear massive because of their disproportionately normal width. Growth plates are not grossly disorganized, and chondrocytes appear normal. Complications can include hydrocephalus and compression of the brain stem, spinal cord, or nerve roots. Minimal impingement by a disc or osteophyte on the small spinal canal can

cause neurologic disturbances. Subcutaneous vosoritide (which is a biologic analogue of C-type natriuretic peptide given once daily under expert supervision) can increase growth in children with achondroplasia,[A2,A3] but its long-term efficacy and safety are unknown. Despite these problems, achondroplasia is compatible with good health and a normal lifespan.[22]

230 APPROACH TO THE PATIENT WITH ALLERGIC OR IMMUNOLOGIC DISEASE

KARI C. NADEAU

Allergic diseases and disorders of the immune system affect multiple organ systems. This chapter addresses approaches to common allergic disorders and inborn errors of immunity. Specific disorders are discussed in detail in the chapters to follow.

ALLERGIC DISEASE

DEFINITION AND EPIDEMIOLOGY

Diseases characterized by hypersensitivity of the immune system and inappropriate reactions to common environmental, food, and drug substances are termed allergic diseases. In the sensitized individual, common foods (e.g., peanut, milk, eggs), airborne particles (e.g., grass pollen, cat dander), drugs (e.g., aspirin, penicillin), insect stings (e.g., bees, wasps), or other agents (e.g., latex, dyes) can trigger an allergic reaction. Reactions can range from mild to severe to life-threatening, and symptoms can occur in one or many organs after skin contact, inhalation, ingestion of allergens, stings, or injections. The prevalence of allergic diseases has increased in recent decades. Although genetics plays a role in their etiology, potential explanations for the increase include improvements in hygiene, increased exposure to environmental pollutants, and alterations in diet and lifestyle. Climate change (Chapter 17) also indirectly plays a role by increasing air pollutants (e.g., wildfires and sandstorms), altering the characteristics of pollens (concentrations, allergenic potential, and composition), and promoting the migration of species.[1]

Allergic diseases can be classified based on the organs that are affected, the type of causal allergen, the interval between the exposure to the allergen and the onset of symptoms, and underlying mechanisms of the reaction. Allergic reactions may be immediate (minutes to 1 to 2 hours) or delayed (hours or days). Traditionally, hypersensitivity reactions have been classified into Type I, II, III, and IV (Fig. 230-1). A more commonly used system classifies allergic reactions into immunoglobulin E (IgE)-mediated, mixed IgE- and cell-mediated, and non-IgE-mediated allergic diseases.[2] IgE-mediated diseases are the best characterized allergic diseases, and reactions with high IgE levels are termed atopic diseases (Table 230-1).

PATHOBIOLOGY

Patients who have IgE-mediated allergic reactions undergo an initial sensitization phase during which IgE antibodies are produced to recognize a specific allergen and are bound to high-affinity FcεRI receptors on mast cells or basophils. Further exposure to allergens can lead to cross-linkage of IgE antibodies with subsequent degranulation of mast cells or basophils. The initial sensitization phase occurs as epithelial cytokines interleukin-25 (IL-25), IL-33, and thymic stromal lymphopoietin are produced in response to the increased permeability of the allergen owing to a loss of integrity in the epithelial barrier. These cytokines enable differentiation of naïve T cells to T_h2 cells as well as upregulation of cytokines (e.g., IL-4, IL-5, and IL-13) and IgE class-switching by B cells. Degranulation of mast cells and basophils leads to the release of histamine and other inflammatory mediators (e.g., cytokines, interleukins, leukotrienes, and prostaglandins) into the surrounding tissue, thereby causing several systemic effects, including vasodilation, the secretion of mucus, eosinophilic infiltration of tissues, and contraction of smooth muscle (E-Fig. 230-1). Atopic sensitization is thought to occur via exposure to allergens through an impaired skin barrier, whereas tolerance is thought to be mediated through the gut. Loss of barrier integrity enables allergens to penetrate and to initiate an inflammatory immune cascade of events that leads to sensitization. The immune dysfunction then further exacerbates the impaired skin barrier to form a vicious cycle.[3] Non-IgE-mediated reactions are poorly defined and are generally T-cell mediated.

ABSTRACT

Allergic diseases are hypersensitivity immune reactions that are associated with inappropriate responses to common environmental, food, and drug substances. Reactions can range from mild to severe to life-threatening, and symptoms can occur in one or many organs after skin contact, inhalation, ingestion of allergens, stings, or injections. The prevalence of allergic diseases has increased in recent decades. Although genetics play a role in the etiology of the disease, current hypotheses for the observed increases include improvements in hygiene, increased exposure to environmental pollutants, and alterations in diet and lifestyle. Allergic reactions may be immediate (within minutes to 1 to 2 hours) or delayed (hours or days).

The more than 400 primary inborn errors of immunity have variable clinical features, including immune deficiency, autoimmunity/autoinflammation, malignancy, or a combination of all three. These conditions should be suspected in patients who have recurrent, persistent, severe, or unusual infections.

TABLE 230-1 COMMON IgE-MEDIATED, MIXED (IgE-MEDIATED AND CELL-MEDITATED), AND NON-IgE-MEDIATED ALLERGIES

DISEASE	APPROXIMATE PREVALENCE	KEY SYMPTOMS	EXAMPLES OF CAUSAL ALLERGENS
IgE-MEDIATED ALLERGIES			
Oral allergy syndrome (pollen-food syndrome)	5 to >20% (children), 10 to 60% (adults)	Rapid onset; tingling and pruritus of the lips, mouth, and oropharynx. Pharyngeal swelling in severe cases	Fresh fruits and vegetables, commonly seen in those with birch, ragweed, or grass pollen allergy
Food allergy	8% (children), 10% (adults)	Rapid onset, abdominal pain, vomiting, hives, wheezing, shortness of breath. Anaphylaxis in severe cases	Food allergens (e.g., egg, peanut, milk)
Anaphylaxis	5% in US (fatal anaphylaxis rare, 1 per million per year)	Rapid onset, progressive, multiorgan. Rapid progression to cardiovascular and/or respiratory collapse in severe cases	Foods (e.g., peanuts, shellfish), drugs, insect stings
Atopic dermatitis	10 to 20%	Pruritus, *Staphylococcus aureus* infection, lichenification, xerosis, excoriations	Foods, aeroallergens, exogenous irritants (e.g., wool, soaps)
Acute, seasonal, and perennial allergic conjunctivitis	5 to 30%	Conjunctivitis, eyelid edema, watery discharge, ocular itching, conjunctival hyperemia	Aeroallergens
Allergic asthma	7%	Chest tightness, shortness of breath, wheezing	Animal dander, mold, house dust mites
Allergic rhinitis	Up to 40% (children), 10 to 30% (adults)	Sneezing, rhinorrhea, lacrimation	House dust mites, grass pollen, tree pollen, animal dander
MIXED IgE-MEDIATED AND NON-IgE-MEDIATED ALLERGIES			
Eosinophilic GI disorders (eosinophilic esophagitis, eosinophilic colitis; eosinophilic gastritis; eosinophilic gastroenteritis)	Eosinophilic esophagitis: 10-60 per 100,000 Eosinophilic gastritis: 6 per 100,000 Eosinophilic colitis: 3 per 100,000 Eosinophilic gastroenteritis: 8 per 100,000	Symptoms dependent on region and nature of eosinophilic infiltration (mucosal, muscular, or serosal) and may include nausea, dysphagia, vomiting, failure to thrive, epigastric pain, food impaction, inflammation of some or all regions of the GI tract	Milk, egg, wheat, soy, peanuts
Urticaria (acute and chronic)	Acute urticaria: 14% Chronic urticaria: 0.1 to 1.5%	Pruritus and raised erythematous cutaneous lesions	Aeroallergens, foods, infections, insect stings, or drugs. Many cases are idiopathic
Atopic keratoconjunctivitis and vernal keratoconjunctivitis	Vernal keratoconjunctivitis: <1 per 10,000 of the population (Europe) Atopic keratoconjunctivitis: 20 to 40% of patients with atopic dermatitis; 5% (Japan)	Clinical symptoms can include photophobia and tearing in addition to commonly noted itching and grittiness as observed in ocular allergy. Ropy mucus, giant papillae, and Trantas dots are also often present. Patients who have atopic keratoconjunctivitis also have concurrent atopic dermatitis	Environmental allergens
NON-IgE-MEDIATED ALLERGIES			
Food protein–induced enterocolitis syndrome	0.35% to 0.7% (cow's milk mediated)	Vomiting, diarrhea, and failure to thrive	Milk, soy
Food protein–induced allergic proctocolitis	0.15 to 17% of infants with isolated rectal bleeding	Rectal bleeding	Cow's milk
Food protein–induced enteropathy	Prevalence unknown	Steatorrhea from malabsorption, diarrhea, and failure to thrive	Cow's milk proteins and soy proteins
Contact dermatitis	Significant variations with causal allergen	Inflammation, skin rash, and blisters	Poison oak, nickel

GI = gastrointestinal; Ig = immunoglobulin.

Specific Types of Allergies

Food Allergy

Food allergy is an immune reaction triggered by common food substances. Exposure to very small amounts of allergenic foods can trigger clinical symptoms, ranging in severity from mild to life-threatening, in one or many organs.[4] The reported prevalence of food allergies is rising.[5] Eosinophilic esophagitis (Chapter 124), food protein–induced enterocolitis syndrome, food protein–induced allergic proctocolitis, and food protein enteropathy (Chapter 126) are among the disorders in which food allergy may play a role.

Drug Allergy

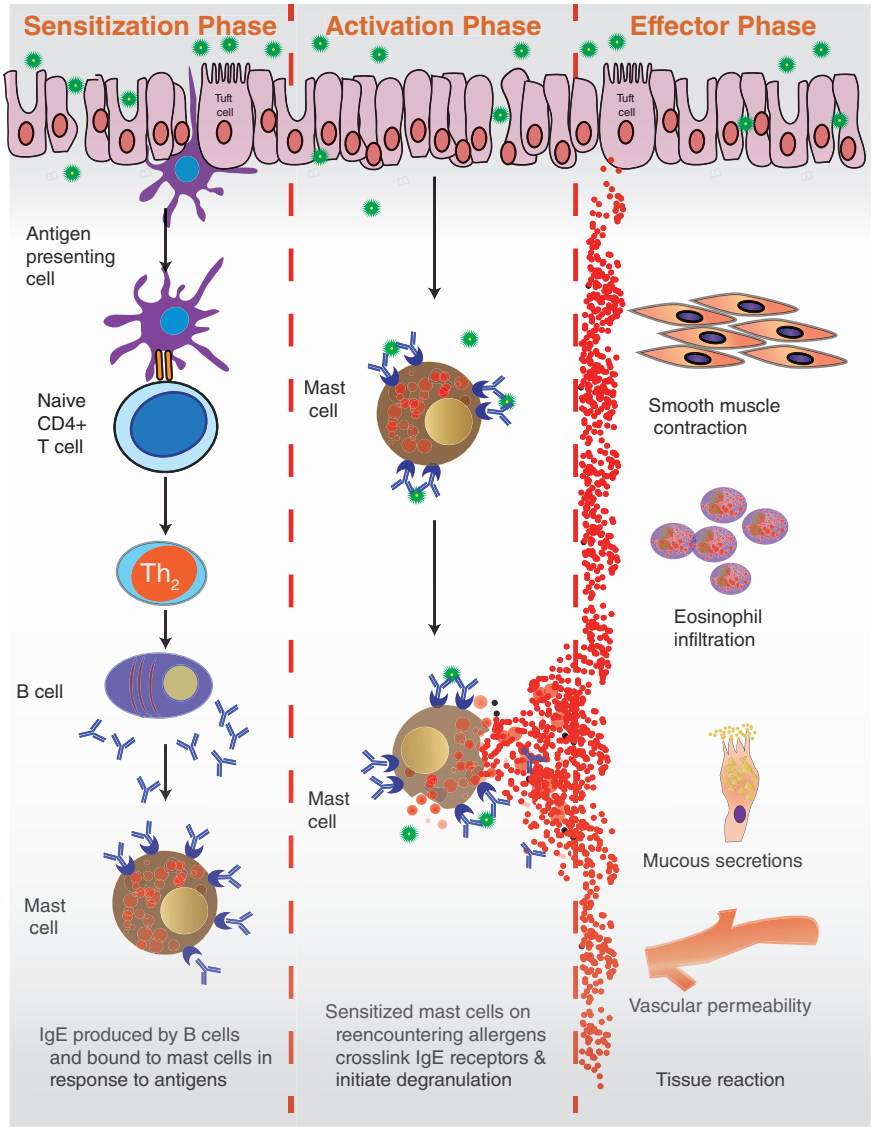
Allergic reactions to drugs (Chapter 234) are a serious public health concern. Drug reactions mediated by immunologic reactions (antibodies or specific T lymphocytes) may occur immediately after exposure to the drug or may be delayed, may affect single or multiple organs, and may be mild, severe, or life-threatening.[6] Risk factors for developing a drug allergy include age (young and middle-aged adults), gender (women), genetic polymorphisms (e.g., human leukocyte antigen), and certain viral infections (e.g., HIV, Epstein-Barr virus). Other factors include increased frequency of exposure and prolonged high doses, intravenous or intramuscular route of administration, high-molecular-weight drugs, and drugs that haptenate tissue or blood proteins.[7]

Environmental Allergy and Occupational Allergy

Outdoor and indoor environmental allergens can sensitize or exacerbate allergic disease (allergic rhinitis, allergic conjunctivitis, and allergic asthma) through IgE-mediated mechanisms. Major indoor aeroallergens are derived from dust mites, cockroaches, cigarette smoking, animal dander (e.g., dog, cat, mice), and mold. Pollutants (Chapter 82) generated from diesel exhaust, gas-burning stoves, fireplaces, or heaters can also exacerbate allergies and asthma. Children who live in close proximity to major highways are more likely to be affected.[8] A number of substances used in different occupations can cause the development of allergic disease affecting the respiratory tract (Chapter 81) and skin. Examples include compounds with both low (dyes, isocyanates, metals) and high (latex, flour) molecular weight. Recurring high levels of exposure are the most important determinants in sensitizing individuals to occupational allergens.

CLINICAL MANIFESTATIONS

Allergic diseases affect different organs, such as the nose, lungs, eyes, gastrointestinal tract, or skin. Symptoms may be limited to one or more organs or, as in the case of anaphylaxis (Chapter 233), may be systemic and be life-threatening. The same allergic sensitization may manifest in different ways at



E-FIGURE 230-1. Mechanism of immunoglobulin (Ig) E–mediated allergic disease. The right column illustrates the various systemic effects of IgE-mediated allergic reactions, including smooth muscle contraction, tissue eosinophilic infiltration, mucus secretion, and vasodilation with vascular permeability.

different times in the same individual. With food allergies, allergic reactions occur within minutes to 2 hours after ingestion of the causal allergen. Oral allergy syndrome is a food allergy that requires prior sensitization to a cross-reacting inhalant allergen. Common symptoms include pruritus of the lips, tongue, and mouth.

Skin

Allergic disorders involving the skin include angioedema, acute and chronic urticaria, and atopic and contact dermatitis (Chapter 407). Symptoms of urticaria and angioedema include pruritus and transient, raised, erythematous cutaneous lesions that range in size from a few millimeters to several centimeters (Fig. 232-2).[9] Urticaria is classified based on time course and etiology. In acute urticaria, wheals and/or angioedema occur for a period of up to 6 weeks, whereas chronic spontaneous urticaria and chronic inducible urticaria are defined as recurrent or persistent lesions for 6 weeks or more.[10] Infections are considered to be the most common cause of acute urticaria, but other triggering factors may include food allergens, food additives, or drugs.

Co-occurrence of angioedema with urticaria is common and is found mainly on the face, lips, mouth, upper airways, and genitalia. Symptoms of acute urticaria or angioedema occur rapidly (often within minutes). Even without treatment, however, individual urticarial lesions typically resolve within 1 to 24 hours.

Atopic dermatitis (Chapter 405) is an IgE-mediated disease that is common in infants and children. In up to 30% of patients the disease has been linked to a loss-of-function mutation in the filaggrin gene, which is essential for skin barrier function. Increased colonization of *Staphylococcus aureus* is seen in more than 90% of patients with atopic dermatitis and may lead to secondary infections. Atopic dermatitis often precedes the development of other atopic diseases, such as food allergy, allergic rhinitis, or allergic asthma.

Allergic contact dermatitis (Chapter 405) is a common skin disease that can be caused by direct contact, airborne particles, vapors, or light.[11] The allergens that mediate allergic contact dermatitis are generally low-molecular-weight substances that combine with skin proteins to form complete allergens inducing innate and adaptive immune responses. Examples include metals (e.g., nickel), plants (e.g., poison oak), or drugs (e.g., neomycin). It is a delayed-type IV, T-cell-mediated, non-IgE reaction to common substances. Clinical manifestations of contact dermatitis vary widely, and multiple subtypes may occur simultaneously. Relapse is common, even with prolonged allergen avoidance.

Eyes

Ocular allergic conjunctivitis[12] includes simple allergic conjunctivitis (acute, seasonal, or perennial), vernal keratoconjunctivitis, atopic keratoconjunctivitis, and giant papillary conjunctivitis (Chapter 391). In simple allergic conjunctivitis, IgE-mediated reaction leads to an immediate or early response (within minutes). Further activation of chemokines leads to late-phase-mediated reactions. Vernal keratoconjunctivitis, atopic keratoconjunctivitis, and giant papillary conjunctivitis, however, appear to be mediated by both IgE and non-IgE cellular pathways.

Ocular allergies can be caused by numerous factors, such as exposure to air pollutants, insects (cockroaches and house dust mites), pet dander, or pollen. Seasonal allergic conjunctivitis and perennial allergic conjunctivitis primarily affect the conjunctiva and possibly the eyelids. In vernal keratoconjunctivitis and atopic keratoconjunctivitis, the cornea is also affected, and vision can become impaired. In seasonal allergic conjunctivitis and perennial allergic conjunctivitis, itching, redness, and swelling of the conjunctiva, along with tearing and discharge of white mucus, is common. One of the main characteristics of vernal keratoconjunctivitis is the presence of giant papillae (several millimeters in diameter) on the upper tarsal conjunctiva and seen easily on the underside of the upper eyelid. Other symptoms include ropy mucus discharge, Trantas dots (aggregation of epithelial cells and eosinophils that appear as gelatinous, mucoid nodules at the superior limbus of the conjunctiva), creasing of the lower eyelids, and pseudomembrane formation on the upper lid. A punctate keratitis may also appear in the central cornea and lead to the formation of a grayish plaque, corneal scarring, and visual impairment. In atopic keratoconjunctivitis, giant papillae and Trantas dots, similar to those found in vernal keratoconjunctivitis, may also be present. However, patients with atopic keratoconjunctivitis are generally older (ages 30 to 50 years) than patients with vernal keratoconjunctivitis (ages 10 years and younger) and often have concurrent atopic dermatitis or a positive family history of atopy. Atopic keratoconjunctivitis and vernal keratoconjunctivitis are two to three times more likely in males than females. Giant papillary conjunctivitis is most commonly seen in conjunction with the use of soft contact lenses, and it is present in approximately 5% of that population.

Upper Airway

Allergic rhinitis[13] affects the upper airways and may be classified as either seasonal (intermittent) or perennial (chronic), with approximately 20% of cases being seasonal, 40% perennial, and 40% with features of both (Chapter 394). Symptoms include sneezing, nasal pruritus, nasal airflow obstruction, and nasal discharge. In seasonal allergic rhinitis, symptoms usually occur in either spring, summer, or fall and are generally associated with pollen from trees, grass, and weeds. Pollen count and type vary with geographic regions. Even within a specific region, changes in weather patterns can cause yearly variations in pollen count and in the overall prevalence and severity of allergic rhinitis. In perennial allergic rhinitis, exposure to indoor and outdoor air pollutants such as pet dander, cockroaches, house dust mites, and molds, should be taken into consideration. In some individuals, seasonal allergies may overlap, thereby leading to perennial symptoms. Approximately 10 to 40% of individuals have concurrent asthma.

Lower Airway

The most common asthmatic phenotype is allergic asthma (Chapter 75), which is a chronic inflammatory disease of the airways. Up to 80% of childhood asthma and more than 50% of adult asthma cases may have an allergic component.[14] Examples of allergens include air pollutants, respiratory viruses, tobacco smoke, drugs, endotoxins, pollen, animal dander, cockroaches, house dust mites, and foods. IgE plays a central role in allergic asthma pathophysiology and has been implicated in both the early (wheezing, shortness of breath, chest tightness, and cough) and late (inflammatory infiltration, bronchoconstriction, and tissue remodeling) phases. Other characteristics include mucosal infiltration by eosinophils, mast cells, and $CD4^+$ T cells. It is a Th2-driven process and high-affinity IgE receptors are observed in inflammatory and resident cells. Allergic asthma is often accompanied by eczema and allergic rhinitis. Other diseases associated with allergic asthma include eosinophilic granulomatosis with polyangiitis (Chapter 249) and allergic bronchopulmonary aspergillosis (Chapter 311).[15]

Gastrointestinal Tract

Allergic inflammatory diseases that affect the gastrointestinal tract include eosinophilic gastrointestinal diseases, food protein–induced enterocolitis syndrome, food protein–induced allergic proctocolitis, and food protein enteropathy. All three are typically present in infancy and are triggered most commonly by cow's milk protein. Symptoms of food protein–induced enterocolitis syndrome include vomiting, lethargy, and dehydration. Patients with food protein–induced allergic proctocolitis present with bloody and mucous stools. Diarrhea, malabsorption, and failure to thrive are observed with food protein enteropathy. These diseases have a favorable prognosis, and most resolve by 3 to 5 years of age.

Eosinophilic esophagitis (Chapter 124) is the most common and well characterized of the eosinophilic gastrointestinal diseases. Symptoms include nausea, dysphagia, vomiting, failure to thrive, epigastric pain, food impaction,[16] and inflammation of the esophagus. Patients with eosinophilic esophagitis often have comorbid atopic diseases such as allergic rhinitis, asthma, food allergy, and atopic dermatitis.

Eosinophilic gastritis, eosinophilic colitis, and eosinophilic gastroenteritis (Chapter 126) are rare and often found in patients who have a history of atopy. Symptoms vary based on region of the gastrointestinal tract affected and extent of eosinophilic infiltration (mucosal, muscular, or serosal). In rare cases, eosinophilic ascites is observed with eosinophilic infiltration into the serosal layer.

Systemic

Anaphylaxis (Chapter 233)[17] is a serious systemic reaction to allergens, is rapid in onset (seconds to minutes), and can quickly progress to cardiovascular and/or respiratory collapse within minutes of inception. Anaphylaxis can be immunologic, nonimmunologic (previously termed anaphylactoid), or idiopathic. Nonimmunologic anaphylaxes are commonly termed complement activation-related pseudoallergy and may be due to activation of complement by nanoparticles, colloidal solutions, or liposomes without the formation of immune complexes. Regardless of the mechanism, all three types are potentially fatal. Anaphylaxis is associated with skin (flushing, urticaria, and angioedema), pulmonary (asthma, laryngeal edema), cardiac (arrhythmia), vascular (hypotension, extravascular fluid loss), gastrointestinal (abdominal

pain, nausea, vomiting, diarrhea), and nonspecific symptoms (metallic taste, sense of impending doom). Common triggers include insect stings, drugs, and food allergens.

DIAGNOSIS

Allergy is a systemic immune disease, and a patient with suspected allergies requires a comprehensive evaluation. A final diagnosis of allergy should be based on correlations among the history, physical findings, and laboratory test results. Because many of the diseases comprise distinct heterogeneous subtypes, a precision medicine approach can guide to personalized diagnosis and treatment.

Patient History

An accurate history is a crucial first step in diagnosing allergic disease. A family history of atopic disease increases risk for allergic disease. The history should include the nature of the patient's symptoms (frequency and severity) and potential exposures to allergens, such as seasonal (e.g., pollen from trees or grasses), perennial (e.g., dust mites, cockroaches), food (e.g., peanuts, tree nuts, egg, raw fruits), environmental (e.g., pets, pollutants, cockroaches, molds, fungi), drug (e.g., penicillin), and occupational (e.g., flour, latex, paints) allergen exposures (Table 230-2). A careful history of exposure, timing of reactions, and clinical symptoms can help narrow the cause of drug allergy because no definitive diagnostic test exists to confirm drug allergy. The use of angiotensin-converting enzyme inhibitors is the leading cause of acquired angioedema, and Blacks are at higher risk.

Physical Examination

Skin should be examined for possible urticaria, angioedema, or atopic dermatitis. Urticarial lesions (Fig. 407-1) typically consist of small, pink, raised, irregular wheals and may be associated with angioedema. Angioedematous lesions are most often found on the face and acral areas. Signs of atopic dermatitis (Fig. 405-5) include flexular papulae, thickening of skin due to hyperkeratinization, excoriations, and lichenification.

The eyes should be examined for signs of excessive tear production, injection and swelling of the palpebral conjunctivae, and swollen or darkened periorbital tissues. Cobblestone papillae may be present.

Internal inspection of the nasal mucosa should be focused on deviations or perforations of the nasal septum, nasal patency, presence of polyps (Figs. 394-3 and 394-4) or foreign bodies, mucosal appearance, and presence and nature of secretions. Decreases in nasal patency caused by swelling of the lower turbinates are often observed (Fig. 394-2). In allergic patients, the nasal mucosa typically appears pale, watery, edematous, and bluish, and secretions are clear and watery to mucoid in nature.

In patients with acute asthma (Chapter 75), clinical examination can help detect wheezing, prolonged expiration, tachypnea, and shortness of breath. Extremities should be checked for cyanosis. Chronic hyperinflation (increased diameter or barrel chest) can be seen in chronic asthma. Wheezing may only be present during expiration (mild or moderate asthma) or during both inspiration and expiration (severe asthma), or it may be absent (when airflow is severely limited or when it predominantly affects the small airways).

Signs of anaphylaxis (Chapter 233) generally include flushing and presence of urticaria and angioedema. Hoarseness caused by upper airway obstruction from angioedema of the tongue, oropharynx, or larynx, or wheezing secondary to asthma, may be observed. Other symptoms may include pruritus, chest tightness, cough, wheezing, rhinitis, sneezing, congestion, rhinorrhea, abdominal pain, uterine cramping, urinary and fecal urgency or incontinence, nausea, vomiting, and diarrhea. Patients may become hypoxic, and anaphylaxis with hypotension may signal shock and cardiovascular collapse.

TABLE 230-2 ALLERGIC DISEASES: SYMPTOMS AND APPROACHES TO TREATMENT

SYMPTOMS	APPROACH TO TREATMENT
Cutaneous: pruritus, rash	H_1-antihistamine
Ocular: gritty sensation, pruritus	Topical H_1-antihistamine or mast cell–stabilizing agent
Upper respiratory: palatal pruritus, clear rhinorrhea, sneeze, nasal obstruction	Topical corticosteroid, oral H_1-antihistamine, leukotriene receptor antagonist, topical nasal H_1-antihistamine
Lower respiratory: wheezing, cough, dyspnea	β_2-Agonist, inhaled corticosteroid, inhaled β_2-agonist, leukotriene receptor antagonist, oral methylxanthine, parenteral corticosteroid, parenteral anti–immunoglobulin E
Gastrointestinal: nausea, vomiting, cramping pain	Epinephrine (if caused by anaphylaxis), oral corticosteroid, oral cromolyn

Laboratory Evaluation

Allergen-specific IgE (sIgE) measurements are the most common diagnostic tool for allergy. Normal values of total IgE do not exclude the presence of allergic disease, and elevated concentrations can be found in persons who smoke and in a number of other diseases besides allergy. In some cases, however, such as allergic bronchopulmonary aspergillosis (Chapters 75 and 311), serum IgE levels may measure the severity of disease or risk for an exacerbation.

Chronic spontaneous urticaria is idiopathic in 80 to 90% of cases, so universal allergy testing for food allergens is not recommended. Fifty percent of patients with chronic spontaneous urticaria test positively for either IgE receptor, anti-FcεRIa, or anti-IgE autoantibodies in the serum. Patients with chronic spontaneous urticaria also have an increased prevalence of autoimmune disorders, such as autoimmune hypothyroidism (Chapter 207), rheumatoid arthritis (Chapter 243), or systemic lupus erythematosus (Chapter 245).

Allergen-specific IgE can be measured either by in vitro blood tests or in vivo tests (skin prick tests and intradermal testing).[18] The specific allergens tested should be based on patient history and environmental exposures. During skin prick tests, a small break in the epidermis (usually forearm or upper back) is made using a lancet or needle to allow penetration of the allergen. In intradermal skin testing, a small amount of the suspected allergen is injected under the surface of the skin. About 15 to 30 minutes after introduction of the allergen, the maximal diameter of both the wheal and the flare is obtained, and results are compared with positive (histamine) and negative (saline) controls. Contraindications include individuals at high risk for anaphylaxis, certain skin conditions such as dermographism, urticaria, cutaneous mastocytosis, and skin affected by atopic dermatitis. Medications that may affect skin prick test results when taken concurrently include antihistamines (including topical forms), tricyclic antidepressants, omalizumab, and topical steroids in the test area. Angiotensin-converting enzyme inhibitors and β-blockers do not interfere with skin prick test results but may be problematic if anaphylaxis occurs and requires treatment.

High-throughput tests for measuring allergen-specific IgE can be used in conjunction with in vivo allergen-specific IgE tests. However, positive results indicate only sensitization to an allergen, not clinically significant allergy. For some types of allergy, such as IgE-mediated food allergy, food challenges under expert supervision can provide a definitive diagnosis (Chapter 126).[19] Component-resolved diagnosis measures sIgE using purified or recombinant components of allergens, such as Ara h2 from peanuts. The basophil activation test measures levels of surface proteins (CD63 and CD203c) that are expressed on stimulation with allergenic proteins. The diagnosis of eosinophilic esophagitis is confirmed when an esophageal biopsy shows at least 15 eosinophils per high-power field.

Non-IgE tests include patch tests and inhalation tests. For allergic contact dermatitis, patch testing is the gold standard for diagnosis. Patches containing potentially allergenic substances (e.g., dyes, latex, metals) are placed on the back for about 48 hours, and a reading is obtained after 72 to 96 hours. Inhalation testing of specific allergens or chemicals may help diagnose occupational allergy or asthma.

Serum tryptase, a mast cell–specific protease, is best biologic marker of anaphylaxis. However, because it has a short serum half-life of 2 hours, tryptase levels should be measured close to the onset of anaphylaxis and again about 2 weeks after recovery. If the baseline tryptase level is elevated, patients are at increased risk for anaphylaxis, especially after an insect sting, and also should be further evaluated for an occult mast cell disorder (Chapter 235).

TREATMENT AND PREVENTION

The current standard of care consists of avoidance of the allergen and the treatment of severe systemic reactions with adrenaline (Chapter 233). Desensitization by an allergy expert is often useful for environmental allergies and is beginning to be used more often for food allergies. The early ingestion of multiple foods during infancy may prevent food allergy by training the immune system to develop tolerance,[A1] and guidelines now suggest early intervention to prevent food allergies in at-risk infants.[20] Mitigation of climate change and air pollution can help prevent further increases in the prevalence of allergic diseases.

INBORN ERRORS OF IMMUNITY

The overall incidence of inborn errors of immunity is about 1:10,000, and the majority present early in childhood. Inborn errors of immunity include more than 400 genetically defined inherited disorders of immunity that can present not only as immune deficiencies but also autoimmunity/autoinflammation, malignancy, or a combination of all three (Chapter 231).[21] Primary immune deficiency diseases include immunodeficiencies that affect cellular and humoral immunity; combined immunodeficiencies with associated or syndromic features; predominantly antibody deficiencies; diseases of immune dysregulation; congenital defects of phagocyte number, function, or both; defects in intrinsic and innate immunity; autoinflammatory disorders; complement deficiencies; bone marrow failure; and phenocopies of primary immune deficiency disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Inborn errors of immunity have highly variable presentations but should be suspected when patients have persistent, severe, or unusual infections. The patient history should include details of infections (age of onset of infections, number, site, and type), including any family history of frequent infections and the presence of other abnormalities, since many primary immunodeficiency diseases are hereditary.

Laboratory Evaluation

Blood counts, including enumeration of total eosinophil, neutrophil, and lymphocyte (T-cell, B-cell, natural killer [NK]-cell) counts, cytokines produced by activated lymphocytes, and determination of serum immunoglobulin levels (IgA, IgE, IgG, IgM) can assist with diagnosis of a suspected immunodeficiency disorder. A significant lymphopenia often can be the first indication of T-cell immunodeficiency. Reduced antibody levels may be indicative of B-cell and antibody immunodeficiency disorders. However, additional tests measuring specific antibody titers in response to defined stimuli (e.g., vaccinations, tetanus toxoid, or pneumococcus) may be useful in patients who have frequent infections and borderline immunoglobulin levels. When defects in neutrophils are suspected, a nitroblue tetrazolium test or dihydrorhodamine response test can assist with diagnosis. The standard screening test for deficiencies in the complement system is the total hemolytic complement assay or CH50. The AH50 can also be used for screening complement abnormalities in the alternative pathway. Targeted panel sequencing, whole-exome sequencing, and whole-genome sequencing under expert guidance have enabled identification of the causative genetic mutations for most inborn errors of immunity and are essential components of the evaluation (Chapter 231).

Chest radiographs can detect thymic shadows and cupping and flaring of the costochondral junction, which can assist with the diagnosis of certain T-cell disorders. An abdominal ultrasound can determine abnormalities of spleen size.

231 PRIMARY IMMUNODEFICIENCY DISEASES

CHARLOTTE CUNNINGHAM-RUNDLES

Primary immune defects affect about 1 per 10,000 persons, but the prevalence rises to 1 per 400 to 1 per 5000 persons when selective immunoglobulin A (IgA) deficiency is included.[1,2] The prevalence has been increasing as the number of known defects has increased to about 450 different entities. Primary immune defects are now classified into nine categories (Table 231-1).[3] The functions of complement (Chapter 37), disorders of phagocytes (Chapter 155), autoinflammatory syndromes (Chapter 240), and bone marrow defects (Chapter 151) are described elsewhere.

TABLE 231-1 CATEGORIES OF PRIMARY IMMUNODEFICIENCY DISEASES

Combined defined defects with syndromic features
Antibody deficiencies
Complement disorders
Phagocyte defects
Immune dysregulation syndromes
Defects of intrinsic and innate immunity
Autoinflammatory defects
Bone marrow failure defects

AN APPROACH TO EVALUATION OF THE IMMUNE SYSTEM

Because of the number and types of immune deficiencies, clinical recognition of the various phenotypes can be difficult, and diagnosis is often delayed. In general, the spectrum of immune defects varies with the age of the patient. Defects of both T and B cells, phagocytes (Chapter 155), immune dysregulation, and innate immunity are more commonly recognized in early childhood, whereas defects of complement (Chapter 37) and the production of antibodies as well as autoinflammatory diseases (Chapter 240) are more commonly diagnosed in adolescents and adults. However, many exceptions exist to this generalization.

For most patients, the first symptom of an immune defect is a series of relatively common infections, particularly chronic sinusitis (Chapter 394), otitis (Chapter 394), bacterial pneumonias (Chapter 85), meningitis (Chapter 381), or osteomyelitis (Chapter 251). In both children and adults with immune defects, infections are likely to persist longer, may require additional courses of antibiotics, and tend to recur. Infections may also lead to additional complications or procedures, such as empyema after bacterial pneumonia or the need for myringotomy tubes in an adult with chronic otitis. In infants and children, chronic infections lead to poor appetite and failure to thrive. For adults, some weight loss may occur, but it usually is less apparent. Because of lack of immunity, reactivated herpes zoster infection (Chapter 346) is relatively common in patients who have T-cell defects or antibody deficiencies. Other common clinical presentations include acute gastrointestinal infections with characteristic organisms such as *Giardia* (Chapter 322) or chronic intestinal inflammatory diseases that lead to malabsorption and weight loss that can mimic gluten intolerance or Crohn disease (Chapters 126 and 127). Depending on the clinical presentation (Table 231-2), a systematic approach (Fig. 231-1)[4] can efficiently guide the evaluation of patients who are suspected of having a primary immune deficiency.

Large gene panels can detect many of the known immune defects. Whole exome or whole genome sequencing can confirm a likely molecular diagnosis in unrelated probands and may influence management in nearly 25% of families.[5] With the advent of genetic testing and its use in clinical medicine, autosomal dominant genes with variable penetrance are increasingly being identified. Importantly, different mutations in the same gene can lead to either loss or gain of function and quite different clinical phenotypes.

SEVERE T- AND B-CELL COMBINED DEFECTS

DEFINITION

Combined immune defects are early-onset diseases in which both the T- and B-cell compartments are greatly impaired. In some conditions, natural killer cells and other cells of the myeloid linage are also abnormal. These disorders often include additional inflammatory features such as autoimmunity and loss of T-cell regulatory function.

EPIDEMIOLOGY

In the United States, universal newborn screening for severe combined immunodeficiency detects these defects in about 1 : 80,000 (E-Table 231-1).[6]

INBORN ERRORS OF IMMUNITY

The overall incidence of inborn errors of immunity is about 1:10,000, and the majority present early in childhood. Inborn errors of immunity include more than 400 genetically defined inherited disorders of immunity that can present not only as immune deficiencies but also autoimmunity/autoinflammation, malignancy, or a combination of all three (Chapter 231).[21] Primary immune deficiency diseases include immunodeficiencies that affect cellular and humoral immunity; combined immunodeficiencies with associated or syndromic features; predominantly antibody deficiencies; diseases of immune dysregulation; congenital defects of phagocyte number, function, or both; defects in intrinsic and innate immunity; autoinflammatory disorders; complement deficiencies; bone marrow failure; and phenocopies of primary immune deficiency disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Inborn errors of immunity have highly variable presentations but should be suspected when patients have persistent, severe, or unusual infections. The patient history should include details of infections (age of onset of infections, number, site, and type), including any family history of frequent infections and the presence of other abnormalities, since many primary immunodeficiency diseases are hereditary.

Laboratory Evaluation

Blood counts, including enumeration of total eosinophil, neutrophil, and lymphocyte (T-cell, B-cell, natural killer [NK]-cell) counts, cytokines produced by activated lymphocytes, and determination of serum immunoglobulin levels (IgA, IgE, IgG, IgM) can assist with diagnosis of a suspected immunodeficiency disorder. A significant lymphopenia often can be the first indication of T-cell immunodeficiency. Reduced antibody levels may be indicative of B-cell and antibody immunodeficiency disorders. However, additional tests measuring specific antibody titers in response to defined stimuli (e.g., vaccinations, tetanus toxoid, or pneumococcus) may be useful in patients who have frequent infections and borderline immunoglobulin levels. When defects in neutrophils are suspected, a nitroblue tetrazolium test or dihydrorhodamine response test can assist with diagnosis. The standard screening test for deficiencies in the complement system is the total hemolytic complement assay or CH50. The AH50 can also be used for screening complement abnormalities in the alternative pathway. Targeted panel sequencing, whole-exome sequencing, and whole-genome sequencing under expert guidance have enabled identification of the causative genetic mutations for most inborn errors of immunity and are essential components of the evaluation (Chapter 231).

Chest radiographs can detect thymic shadows and cupping and flaring of the costochondral junction, which can assist with the diagnosis of certain T-cell disorders. An abdominal ultrasound can determine abnormalities of spleen size.

Other common clinical presentations include acute gastrointestinal infections with characteristic organisms such as *Giardia* (Chapter 322) or chronic intestinal inflammatory diseases that lead to malabsorption and weight loss that can mimic gluten intolerance or Crohn disease (Chapters 126 and 127). Depending on the clinical presentation (Table 231-2), a systematic approach (Fig. 231-1)[4] can efficiently guide the evaluation of patients who are suspected of having a primary immune deficiency.

Large gene panels can detect many of the known immune defects. Whole exome or whole genome sequencing can confirm a likely molecular diagnosis in unrelated probands and may influence management in nearly 25% of families.[5] With the advent of genetic testing and its use in clinical medicine, autosomal dominant genes with variable penetrance are increasingly being identified. Importantly, different mutations in the same gene can lead to either loss or gain of function and quite different clinical phenotypes.

SEVERE T- AND B-CELL COMBINED DEFECTS

DEFINITION

Combined immune defects are early-onset diseases in which both the T- and B-cell compartments are greatly impaired. In some conditions, natural killer cells and other cells of the myeloid linage are also abnormal. These disorders often include additional inflammatory features such as autoimmunity and loss of T-cell regulatory function.

EPIDEMIOLOGY

In the United States, universal newborn screening for severe combined immunodeficiency detects these defects in about 1 : 80,000 (E-Table 231-1).[6]

ABSTRACT

About 450 inborn genetic defects of the immune system are described, and others will certainly be identified in the future. The overall incidence of primary immunodeficiency diseases is estimated to be about 1 in 10,000, excluding selective IgA deficiency, but this estimate is likely low. These gene defects lead to abnormalities of structure or function of lymphocytes, monocytes, phagocytic cells, and the complement proteins, and they may result from systemic defects that impinge upon the immune system. Primary immune defects may be diagnosed in infants, children, or adults of all ages. Although the spectrum of molecular defects may vary, the clinical findings (infection, immune dysregulation leading to inflammation and/or autoimmunity) are similar, regardless of the age of the patient. For unknown reasons, more than 50% of the reported immune defects (excluding IgA deficiency) lead to defects in antibody production. Although the exact categorization of immune defects is arbitrary, primary immune deficiencies are now grouped into nine main themes, according to the predominant cell systems or mechanism(s) that are defective: T- and B-cell combined deficiencies, combined defined defects with syndromic features, antibody deficiencies, complement disorders, phagocyte defects, immune dysregulation syndromes, autoinflammatory defects, defects of intrinsic and innate immunity, and bone marrow failure syndromes.

severe combined immunodeficiency (SCID)
common variable immunodeficiency (CVID)

E-TABLE 231-1 EXAMPLES OF SEVERE COMBINED IMMUNE DEFECTS

SCID TYPE	GENES	INHERITANCE	LABORATORY FEATURES	DISEASE AND COMPLICATIONS
Defects of V(D)J recombination	*RAG1, RAG2* *DCLREIC* DNA-PKcs	Autosomal recessive	Very low lymphocyte numbers with loss of T and B cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky versions may have autoreactive T cells (Omenn syndrome)
Adenosine deaminase deficiency	*ADA*	Autosomal recessive	Variably low lymphocyte numbers with loss of T and B cells; also decreased NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; often with costochondral junction flaring, neurologic features, hearing impairment, lung and liver manifestations
X-linked severe combined immunodeficiency	*IL2RG*	X-linked	Low lymphocyte numbers with loss of T cells; B cells present; markedly decreased NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome
JAK3 deficiency	*JAK3*	Autosomal recessive	Low lymphocyte numbers with loss of T cells; B cells present; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with variable T or NK cells
IL-7 deficiency	*IL7RA*	Autosomal recessive	Low lymphocyte numbers with loss of T cells; B cells present; normal NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome
T-cell receptor chain defects	γ-, ε-, and ζ-chain mutations	Autosomal recessive	Low lymphocyte numbers due to loss of T cells; normal B and NK cells; hypogammaglobulinemia	Severe infections, failure to thrive; leaky cases may present with low T or NK cells or Omenn syndrome

DNA-PKcs = DNA-dependent protein kinase catalytic subunits; IL-7 = interleukin-7; JAK3 = Janus kinase 3; NK = natural killer; SCID = severe combined immunodeficiency.

TABLE 231-2 CLINICAL PRESENTATION AND EVALUATION OF THE IMMUNE SYSTEM

CLINICAL PRESENTATION	DEFECTS	IMMUNE DEFECTS	CONDITIONS	LABORATORY TESTING
Recurrent or chronic bacterial, viral, or fungal infections Opportunistic infections	Cell-mediated immunity	Impaired killing of intracellular organisms Impaired viral immunity Hypogammaglobulinemia	Severe combined immunodeficiency and other combined syndromes	Absolute lymphocyte count Enumeration of T cells and T-cell subsets Proliferative tests for T-cell function Low immune globulins; no antibody
Bacterial infections Viral infections Autoimmunity Lymphoid hypertrophy Inflammatory diseases Enteropathy Giardiasis	B cells	Hypogammaglobulinemia Impaired bacterial killing Impaired clearance of virus Autoimmunity	Hypogammaglobulinemia Agammaglobulinemia IgA deficiency Common variable immune deficiency IgG subclass defects Antibody deficiency	Enumeration of B cells Serum IgG, IgA, and IgM Antibody testing (e.g., tetanus, diphtheria) Vaccine challenge and antibody testing (e.g., tetanus, diphtheria pneumococcal vaccine)
Bacterial infections Susceptibility to meningococcal disease Autoimmunity Angioedema	Complement	Impaired opsonization Impaired bacterial killing Lack of clearance of immune complexes	Complement C2 deficiency Other complement defects Hereditary angioedema	CH_{50} AH_{50} Measure individual complement components C1 inhibitor protein and function
Bacterial infections Poor skin healing Fungal infections Stomatitis Periodontal disease	Phagocytic cells	Impaired neutrophil mobilization Impaired opsonization Impaired bacterial killing	Chronic neutropenia Cyclic neutropenia Autoimmune neutropenia Leukocyte adhesion deficiency Chronic granulomatous disease	Absolute neutrophil counts Neutrophil oxidative burst examined by dihydrorhodamine test by flow cytometry Examination of the blood smear Antineutrophil antibodies

AH_{50} = alternative hemolytic complement; CH_{50} = total hemolytic complement; Ig = immunoglobulin.

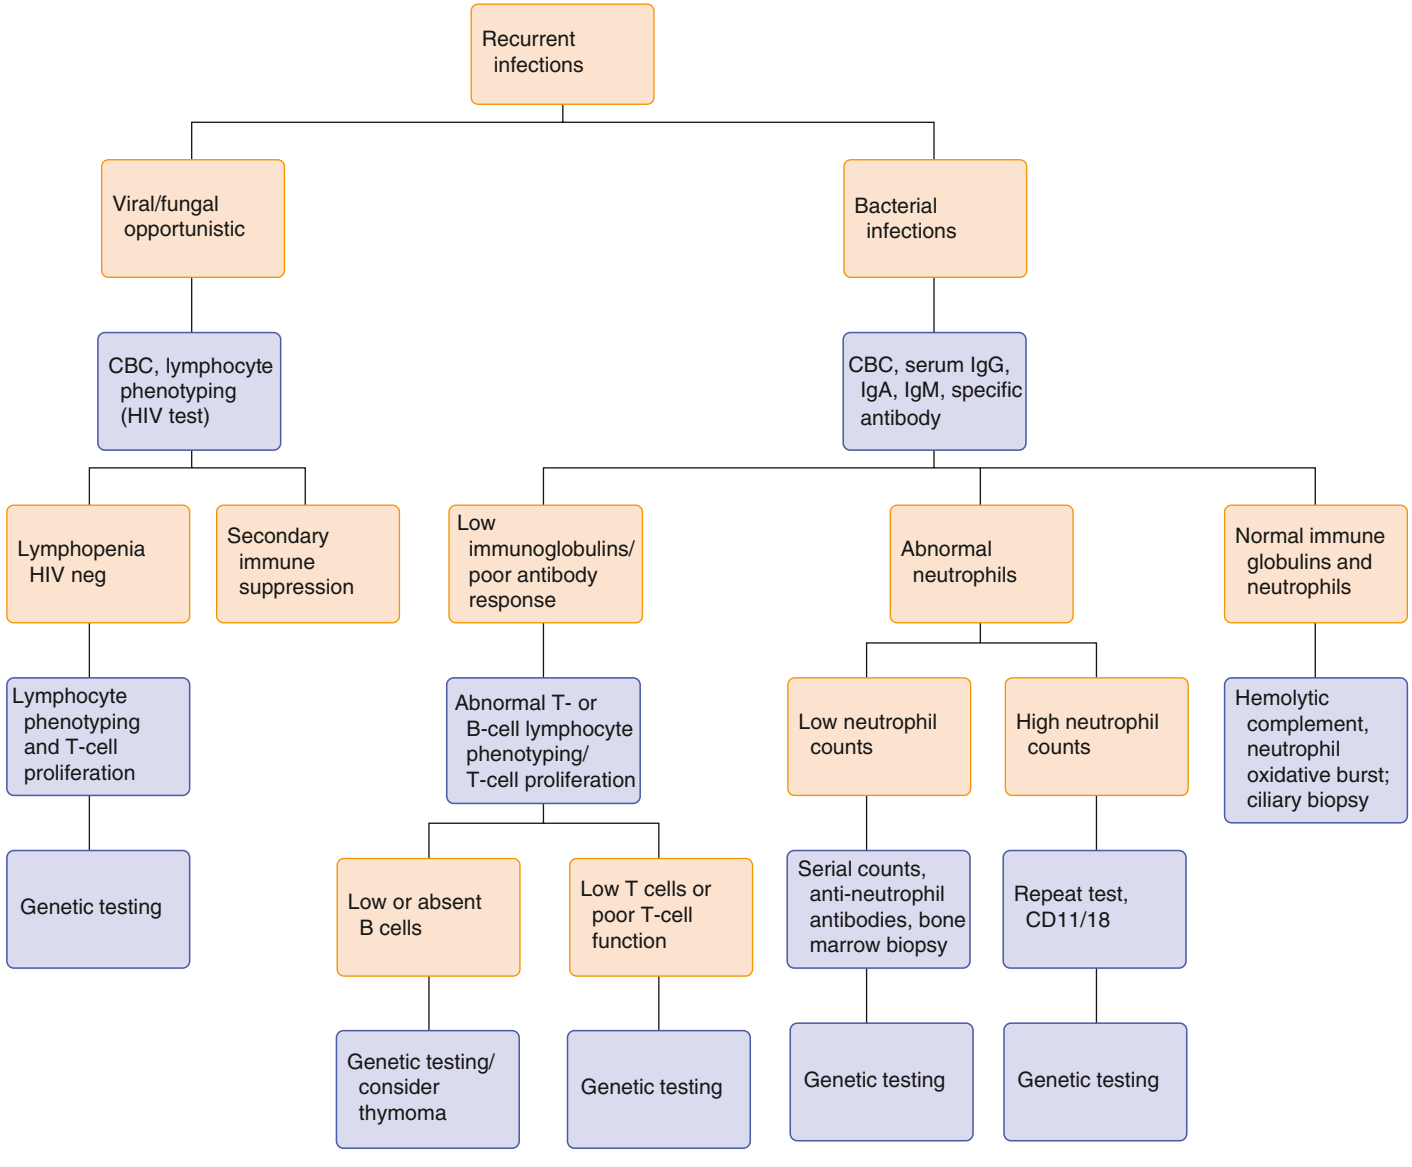

FIGURE 231-1. **Evaluation of immune defects presenting with recurrent infections.** CBC = complete blood count; HIV = human immunodeficiency virus; Ig = immunoglobulin.

PATHOBIOLOGY

The hallmark of combined defects is that they eliminate or greatly impair T-cell development, in most cases leading to profound lymphopenia. Infants with disorders that affect the formation of T- and B-cell receptors, such as when defects of the recombinase activating genes *RAG1* and *RAG2* impair VDJ recombination, have few if any T and B cells. Similarly, other defects of DNA recombination or repair genes (ARTEMIS, the product of *DCLREIC*, and DNA-PKcs) will have a similar phenotype. When T-cell immunity is absent, B cells may be present, but they will have no function, as is the case for severe combined X-linked immunodeficiency due to mutations in the cytokine γ chain, which is an essential signaling component of six cytokine receptors (interleukin [IL]–2, IL-4, IL-7, IL-9, IL-15, and IL-21). Defects of the *JAK3* gene, which is downstream from the cytokine γ chain, or of the IL-7 receptor itself lead to a similar immune profile.

CLINICAL MANIFESTATIONS

With loss of both essential limbs of the adaptive immune system, infants with combined immune defects have severe and recurrent infections that are caused by bacteria, viruses, and fungi. Other common features include diarrhea, dermatitis, and failure to thrive. Clinically, most patients present before the age of 3 months, but a significant number of infants may present later, although still usually in the first year of life. Without intervention, severe combined immunodeficiency commonly results in debilitating infections and death by age 2 years. In some cases, the immune defect is such that a few T cells can develop, but these cells are often self-reactive; such cases are often termed "leaky" severe combined immunodeficiency. When the presentation of these cases includes rashes and evidence of autoimmunity, infants are said to have Omenn syndrome.

DIAGNOSIS

All newborns in the United States are now examined by sensitive and specific DNA-based screening for severe combined immunodeficiency,[7] so the disease is now typically diagnosed before any symptoms have appeared. Newborns normally have a mean absolute lymphocyte count of 4000/μL or higher, but most infants with severe combined immunodeficiency have significant lymphopenia. A flow cytometry panel will enumerate T, B, and natural killer (NK) cells and suggest the genes that may be responsible. Further genetic testing is commonly performed. Less severe forms of combined immune deficiency (E-Table 231-2) are not identified by newborn screening because T cells are present.

TREATMENT AND PROGNOSIS

Early immune reconstitution with stem cells from human leukocyte antigen (HLA)–matched bone marrow or mobilized peripheral blood is mandatory. When the diagnosis is made early and no severe infections have occurred, hematopoietic stem cell transplantation (Chapter 163) is likely to be curative in 90% of selected cases.[8] Gene therapy also can be used for several primary immunodeficiencies, including forms of severe combined immunodeficiency (e.g., adenosine deaminase deficiency)[9] as well as Wiskott-Aldrich syndrome. For infants with severe combined immunodeficiency, lentiviral vector gene therapy combined with low-exposure, targeted busulfan conditioning can result in multilineage engraftment, reconstitution of functional T cells and B cells, and normalization of natural killer cell counts for at least 16 months with low-grade side effects.[10] Gene editing to repair the endogenous gene so it can be expressed under normal regulatory controls is an experimental procedure.

LESS SEVERE T- AND B-CELL COMBINED DEFECTS

In addition to the severe forms of severe combined immunodeficiency, a number of other genetic defects also impair both T- and B-cell limbs, but newborn screening may not identify these infants because the number of T-cells might not be sufficiently reduced. In these forms, in addition to infections, the phenotype may include not only susceptibility to bacterial infection but also atopy, severe viral infections, autoimmunity, and, in some, cancer (E-Table 231-2).

Examples of these less severe T- and B-cell combined defects include syndromes in which major histocompatibility complex (MHC) class I or class II is not expressed (sometimes called bare lymphocyte syndromes), additional defects of T-cell signaling (such as Zap-70), and syndromes that result when defects of the actin cytoskeleton prevent T-cell activation, including the dedicator of cytokinesis proteins, DOCK2 and DOCK8.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

As with the more severe combined immunodeficiency states, these syndromes lead to defects of both T- and B-cell compartments, and infants present with severe and recurrent bacterial, viral, or fungal infections; diarrhea; dermatitis; and usually failure to thrive. One notable example, with atopic disease and high immunoglobulin E (IgE), is DOCK8 deficiency, which was first recognized in babies with autosomal recessive hyper-IgE syndrome (E-Table 231-2).

TREATMENT AND PROGNOSIS

Hematopoietic transplantation is the only curative measure.

COMBINED DEFECTS WITH SYNDROMIC FEATURES

Another group of combined primary immune defects has distinctive systemic characteristics, aside from the obvious abnormities in the immune system (Table 231-3). The best known of these are Wiskott-Aldrich syndrome, ataxia-telangiectasia, DiGeorge syndrome, hyperimmunoglobulin E (Buckley-Job) syndrome, cartilage-hair hypoplasia, and purine nucleoside phosphorylase (PNP) deficiency.

WISKOTT-ALDRICH SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

Wiskott-Aldrich syndrome is an X-linked recessive disease that is characterized by eczema, thrombocytopenia, and immune deficiency. Wiskott-Aldrich syndrome is rare, estimated at 1 to 10 cases per million males. Ethnic differences are not known.

The syndrome is caused by mutations in the *WAS* gene, which codes for the Wiskott-Aldrich syndrome protein that is an intracellular cytoplasmic scaffold protein important for the activation and mobility of all blood cells. This protein is involved in the polymerization of actin and in establishing an interface between immune cells (the immune synapse). Partly depending on the location of the mutation in the *WAS* gene, milder versions lead to X-linked thrombocytopenia in some cohorts. Another, much rarer version leads to X-linked neutropenia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The main manifestations in early childhood include eczema, chronic thrombocytopenia sometimes leading to bloody diarrhea, and immune deficiency with recurrent infections. Autoimmunity or inflammatory diseases, including autoimmune hemolytic anemia, splenomegaly, arthritis, inflammatory bowel disease, and vasculitis can be present. The incidence of lymphoma is also increased. Family history may include male relatives with Wiskott-Aldrich syndrome or thrombocytopenia.

The diagnosis is commonly made in the first few years of life in males who have the characteristic eczema as well as thrombocytopenia that leads to petechiae. IgM levels are typically low, whereas IgA (and sometimes IgE) levels are increased. Platelet sizes are smaller than normal, and clot retraction is poor. The diagnosis can be suggested by lack of the Wiskott-Aldrich syndrome protein as detected by flow cytometry, but definitive diagnosis requires gene testing.

TREATMENT

Treatment strategies for Wiskott-Aldrich syndrome are diverse and usually determined by experts on a case-by-case basis.[11] Conservative management includes prophylactic antibiotics, immunization with conjugated polysaccharide vaccines, and intravenous or subcutaneous immune globulin for patients who have repeated infections. For eczema, standard measures are used (Chapter 405). Lifelong antibiotic prophylaxis is mandatory. Thrombopoietic agents, such as eltrombopag and romiplostim, can be helpful.[12] Platelet transfusions should be reserved for active bleeding that cannot be managed with usual methods (e.g., aminocaproic acid) and should be avoided in patients for whom hematopoietic stem cell transplantation is being considered. Splenectomy is discouraged because of the risk of post-splenectomy sepsis. Autoimmunity can be difficult to control, and immune suppression should be used with caution. Treatment of lymphomas is by standard regimens (Chapter 171).

Hematopoietic stem cell transplantation (Chapter 163) can be curative. Trials with gene therapy are also ongoing.

E-TABLE 231-2 EXAMPLES OF LESS SEVERE COMBINED IMMUNE DEFECTS

SCID TYPE	GENES	INHERITANCE	LABORATORY FEATURES	DISEASE AND COMPLICATIONS
MHC class I deficiency	*TAP1, TAP2; TAPBP; β2M*	Autosomal recessive	Low CD8, normal CD4, absent MHC I on lymphocytes	Vasculitis, pyoderma gangrenosum; granulomatous disease
MHC class II deficiency	*CIITA; RFXANK*	Autosomal recessive	Low CD4 cells Absent MHC II expression on lymphocytes	Failure to thrive, respiratory and gastrointestinal infections, liver/biliary tract disease
ZAP-70 deficiency	*ZAP-70*	Autosomal recessive	Low CD8, normal CD4 number but poor function	May have immune dysregulation, autoimmunity
